1. Introduction

An abrasive has been defined as "any of a wide variety of natural or manufactured substances used to grind, wear down, rub away, smooth, scour, clean or polish, often combined with a binder to make grinding wheels or affixed with glue to the surface of paper or cloth" [1].

Although this broad definition could include such products as plastic pads, metal wool, pumice, and various tools employing large single diamonds, as in bits for oil-well drilling, this article is limited to granular abrasives as hard as, or harder than, quartz (crystalline silicon dioxide) with grit sizes from about 5 mm average diameter down to 1 µm or smaller. The abrasives can be used in their loose, bonded (grinding wheel), or coated (sandpaper) forms.

Abrasives have applications that are so extensive and varied that only the major ones are mentioned in this article. For further information see [2–12]. In addition major manufacturers of abrasives, bonded and coated products, and related trade organizations have their own brochures, reprints of published articles, etc., available on almost any aspect of the application of their products. Most of them, as well as some universities and miscellaneous organizations, also have Internet sites.

2. Natural Abrasives

2.1. Quartz

Quartz [*14808-60-7*] is found worldwide. Major applications include the abrasive for common flint sandpaper used industrially for the finishing of nonmetallic substances, such as leather and felt, and also for miscellaneous household applications. Other uses are in sandblasting, in lapping of soft materials, as the cutting medium in wire sawing of soft stone, such as marble, and in scouring compounds. The use of this abrasive has declined greatly because inhalation of free silica dust may lead to silicosis. Quartz has been replaced to a considerable extent by manufactured abrasives, such as fused aluminum oxide and silicon carbide, as well as by garnet, glass, and slags.

10.1002/14356007.a01_001

2.2. Garnet

Mineralogically, the term garnet refers to a group of minerals with similar crystal structure but varying considerably in chemical composition. Most abrasive garnet is almandite [*1302-62-1*], an iron aluminum silicate, $Fe_3Al_2(SiO_4)_3$.

Almost all of the garnet used for high-performance coated abrasives is mined in the Adirondack area of New York State. The ore is crushed and beneficiated and the resulting garnet is separated into various grit sizes and heat treated. This particular garnet is unique, as the mineral fractures to produce grains having sharp, continuous edges that are optimum for use as a coated abrasive. Also its hardness is at the upper end of the range for garnets. The coated product is used for finish sanding of wood in furniture and woodworking plants.

Other U.S. operations in New York, Idaho, and Maine, and those elsewhere in the world, produce garnet of inferior quality for coated applications, but which is used extensively for sandblasting, metal lapping, and the fine grinding of glass.

Estimated 1996 world production in 10^3 t/a are [49]:

United States	68.2
India	15
Australia	40
China	15
Others	16.8
Total	155

Approximately 30 % of U.S. production was used for water-filtration applications.

2.3. Corundum and Emery

Corundum [*1302-74-5*] is a naturally occurring aluminum oxide mineral of high purity. Estimated production in 1990 in 10^3 t/a was [50]:

South America	0.25
Europe + CIS	10
Africa	20
Asia (India)	2
World total	32.25

The major use of corundum is for the loose-grain grinding and polishing of optical components.

Emery [*12415-34-8*] consists predominantly of corundum but also contains varying amounts of other minerals, particularly magnetite [*1309-38-2*] and hematite [*1317-60-8*]. High-quality emery has been produced on the Greek island of Naxos for at least 2000 years and also is mined in Turkey. Major uses include polishing metals with the coated products and incorporation of the abrasive in nonslip floors, pavements, and stair treads.

The term "emery" has also been applied to a rock mined near Peekskill in New York State. Also known as spinel emery, it contains little or no corundum. However, because of its content of spinel [*1302-67-6*], a mineral with hardness between quartz and corundum, this "emery" has utility in less demanding applications. Very little, however, is used for coated abrasives.

Estimated world emery production in 1990 was 20 000 t/a and has decreased sharply since 1983.

2.4. Diamond

Diamonds [*7782-40-3*] apparently were found first in India and Borneo over 2000 years ago, but the discovery of them in South Africa in 1866 began an era of great expansion that is still continuing (→ Carbon).

Diamonds may be classified as gem quality, high-grade industrial, and bort, the borderlines between grades overlapping and varying with demand. Bort contains inclusions, microcracks, and other flaws, giving rise to translucency or opacity, off-color, etc. The material therefore is used almost exclusively in grain and powder forms. Most natural diamonds are single crystals, but carbonado [*12414-51-6*], a type found in Brazil, and ballas, found in Brazil and Africa, are polycrystalline in structure. They are especially tough because of the absence of well-developed cleavage planes, and are particularly useful for heavy-duty applications, such as truing and dressing grinding wheels.

World production of natural industrial diamonds in 1996 in 10^6 carats, including bort, which accounts for over 85 %, was:

Congo (Kinshasa)	15
Russia	9.2
Botswana	5
Republic of South Africa	6
Australia	23.1
All others	3.3
Total	61.6

Australia is the worlds largest producer since the startup of the Argyle alluvial operation in Western Australia in January 1983.

Major uses of diamonds are discussed in Section 3.6.

3. Manufactured Abrasives

3.1. Fused Aluminum Oxides

Differences in the composition of natural corundum and emery gave rise to variability in grinding wheel manufacture and in end-use performance. Therefore attempts were made to produce more consistent synthetic corundum abrasives.

Although some early work was carried out in Europe, the first commercially successful product resulted from the experiments of C. B. Jacobs, C. M. Hall, and A. C. Higgins in the United States at the end of the 19th century and the beginning of the 20th [13]. This technology was the foundation for a variety of fused aluminum oxide [*1344-28-1*] abrasives (→ Aluminum Oxide).

3.1.1. Raw Materials

Bauxite [*1318-16-7*] is used directly for the production of some fused alumina types, and indirectly, through the Bayer process, for other varieties. Largely for economic reasons, bauxites used for the production of fused aluminum oxide abrasives are of relatively high Al_2O_3 content. Materials from various sources are usually blended, a typical specification being:

Al_2O_3* = 82 % minimum
SiO_2 = 8 % maximum
Fe_2O_3 = 8 % maximum
TiO_2 = 4 % maximum

* determined by subtracting total SiO_2, Fe_2O_3, and TiO_2 from 100 %.

Abrasive-grade bauxite consumption in the United States and Canada was quoted as 197×10^3 t in 1994 and 133×10^3 t in 1995, both on a dry basis. This is less than 2 % of the total consumption of bauxite, 90 % of which was used for the production of aluminum.

The alumina from the indirect Bayer process contains about 99 % Al_2O_3. The type commonly used for fused alumina production contains approximately 0.4 – 0.5 % Na_2O, the remainder being small amounts of SiO_2, Fe_2O_3, and water.

3.1.2. Furnace Designs

Two general types of furnace are employed, one resulting in a batch process and the other in a continuous one.

The first, generally known as the *Higgins furnace*, consists of an open-ended, slightly tapered cylinder of sheet steel, smaller diameter up, resting on a hearth protected by a carbon coating [14]. Fusion of the bauxite is accomplished using an electric arc. Water continuously flows down the outside of the shell, keeping it from melting during the process. After fusion is complete, the product is cooled for several days, resulting in a coarsely crystalline material. This is sorted and rough crushed to yield crude abrasive about 50 mm in size.

Continuous furnaces are patterned after the batch type except that they are generally much larger and arranged for tilting and tapping the molten products into suitable containers [15], [16]. For economic reasons most fused aluminas being produced in similar large-capacity casting furnaces where fusion may continue uninterruptedly for many days or even months.

3.1.3. Fused Alumina Types

The fused alumina produced in largest tonnage is known as *regular aluminum oxide*. The raw materials are calcined bauxite, carbon usually in the form of coke, and iron borings, a typical mass ratio being 80 : 15 : 5. Because the relative ease of reduction of the bauxite feed to metal in the fusion process with carbon is $Fe_2O_3 > SiO_2 > TiO_2 > Al_2O_3$, an abrasive of considerably higher Al_2O_3 content than that of the furnace feed can be attained. During fusion two immiscible liquids exist. The upper one becomes the abrasive on crystallization, and the lower one becomes a byproduct, ferrosilicon.

Regular aluminum oxide is brown and has a chemical composition of approximately 95 %

Al_2O_3, 1.5 % SiO_2, less than 0.5 % Fe_2O_3, and 3 % TiO_2. Because of very slow cooling in the Higgins furnace, the crystals of alumina are coarse, averaging 10 – 15 mm in diameter. If the fused material is cast, the upper liquid must be poured into very large molds holding at least 5 t of product to insure similar slow cooling and coarse crystallization.

A second brown type is *semifriable fused alumina*. It is purer than regular, containing approximately 97 % Al_2O_3, 0.5 % SiO_2, less than 0.5 % Fe_2O_3, and 2 % TiO_2. Both batch and continuous processes are used to produce this variety.

Because the regular and semifriable types are close in composition, the present trend is toward a single brown fused alumina of intermediate composition, produced in casting furnaces. The relative friabilities are adjusted by crushing and processing methods to give different grain shapes, the more equidimensional being the regular and the sharper, less blocky being the semifriable.

In general, the major use of fused alumina abrasives is for processing high-tensile-strength ferrous metals, such as carbon steels. The regular kind is employed in loose-grain form in blasting, lapping, and barrel finishing, in bonded form mostly in nonprecision operations, such as cutting off and rough grinding in organic-bonded products. Semifriable alumina is more commonly used in vitrified-bonded products for precision grinding operations, and on coated belts and discs.

A third type, similar in composition and fusion method to the above, is known as *microcrystalline*. In order to produce an abrasive with very small alumina crystals, rapid cooling of the melt is required. This is effected by pouring it into small molds or onto pans to produce slabs. The resulting abrasive has higher intrinsic strength than the others. It formerly was used extensively in heat-treated form for very heavy duty grinding wheel applications, such as the conditioning of steel slabs and billets using resin-bonded products. For the most part this abrasive has been superseded by fused zirconia – alumina of the ZS type (Section 3.2), or by sintered alumina of the 76 Alundum type (Section 3.3).

White fused alumina is produced by direct fusion of Bayer process alumina [14]. Either the batch or the continuous casting process may be employed. Because the raw material is of high purity, only fusion and crystallization take place. The resulting abrasive has about the same chemical composition as the alumina. However, a small amount of the soda is volatilized, giving rise to pores in the resulting product. Sometimes small amounts of chromium oxide [*1308-38-9*] are added to the furnace feed, producing a pink or ruby-colored abrasive. Similarly, a small addition of vanadium oxide [*1314-34-7*] results in an emerald green color. Although claims have been made for the value of such additions, controlled grinding tests have failed to detect positively any advantages. The major use for the white abrasive is in vitrified-bonded wheels for toolroom grinding or precision grinding of heat-sensitive steels.

Monocrystalline aluminum oxide is a very high purity abrasive, produced directly from bauxite in a single-stage fusion [17]. The preferred method employs a furnace feed consisting of bauxite, pyrite (FeS_2) [*1309-36-0*] or sulfur [*7704-34-9*], carbon, and iron borings. When subjected to fusion in the Higgins batch furnace, two immiscible liquids are formed as with regular aluminum oxide. However, in the present case very slow cooling of the upper liquid results in essentially pure, individual crystals of Al_2O_3 in a matrix of sulfides. After the pig has cooled and been crushed, the matrix is removed chemically and mechanically. This treatment releases alumina crystals in the range of sizes required by the industry.

Little or no crushing is needed, so in this respect this abrasive is entirely different from all the other types of fused aluminas in use today. Chemical analysis approximates 99.2 % Al_2O_3, 0.6 % TiO_2, 0.2 % impurities. This abrasive also may be produced in a casting furnace provided that the fusion is poured into a large receptable capable of holding many tons of product to permit slow cooling of the melt. The size distribution of the resulting abrasive crystals can be varied by changes in manufacturing parameters. Surprisingly the monocrystalline type also may be produced from a mixture of Bayer process alumina, elemental sulfur, and carbon [18]. In this process only one liquid is present in the furnace during fusion, but otherwise the sequence of operations is similar, and the resulting product is the same as that produced directly from bauxite. This premium-priced abrasive is found to be more cost efficient than others, such as the

semifriable type, in many precision operations using vitrified-bonded wheels.

Production. World production capacity for fused aluminum oxide is listed in Table 1.

Table 1. World production capacity (10^3 t/a) for fused aluminum oxide in 1996 and 1997 (estimated) [49]

Trade Names: Alundum, Aloxite, etc.

3.2. Fused Zirconia – Aluminas

The most outstanding commercial development in the area of alumina-containing abrasives in the last two decades was the invention of fused zirconia – alumina products. For the applications in which they are most useful, they result in substantially greater efficiencies (lower total grinding costs) than the fused aluminas previously employed. United States and Canadian production for 1980 was 17.2×10^3 t, amounting to 11 % of all fused aluminas, including the zirconia – aluminas. No production data were available for 1981 or 1983; however, 1982 production was quoted as 7.3×10^3 t or 6 % on the same basis as the 11 % for 1980. This reduction was caused by the severe depression in those segments of the metal-working industry in which zirconia – alumina abrasives are most applicable.

These abrasives also are produced in Japan, France, Austria, Federal Republic of Germany, and possibly other countries. However, production data are not available for them.

Zirconia Content 25 wt %. Although the basic patent specified an abrasive alloy consisting essentially of zirconium oxide [*1314-23-4*] and aluminum oxide, with the content of the former between 10 and 60 wt %, the resulting commercial product typically contains about 25 % [19]. The alumina may be derived from bauxite or from the Bayer process, and the zirconia from the mineral zircon (a zirconium silicate) [*14940-68-2*], baddeleyite (a naturally occurring mineral high in ZrO_2) [*12036-23-6*], or fused zirconium oxide. Zirconia and alumina are fused by electric-arc casting furnaces to give primary crystals of alumina with diameters no greater than about 300 µm but typically less than 30 µm in a matrix of a eutectic of alumina and zirconia. The resulting abrasive is dense and very tough. The grains dull slowly during heavy-duty grinding operations, as with resin-bonded wheels on floorstand machines in foundries. They also have a longer life on high-speed, high-pressure grinders used for conditioning billets and slabs, particularly those made of alloy steels or of stainless steel, where better surface finish is required than produced by the sintered alumina of the 76 Alundum type (Chap. 3.3.).

Trade Names: ZF-ZS Alundum, BX, BZ, etc.

Zirconia Content 40 wt %. The raw materials and fusion methods are similar to those discussed above; however, in this case the melt must be solidified very rapidly in order to produce extremely small crystals [20]. In addition to a relatively slow dulling rate, these grains tend to fracture to a greater extent than the 25 % analogue and do so in such a manner as to provide new cutting edges rather than being shed from the grinding wheel or coated abrasive product. Major applications include resin-bonded portable wheels, cones and plugs, cloth-backed resin-bonded belts, and fiber-backed discs for grinding castings of steel, gray and ductile iron, and stainless steel alloys. In some cases mixtures of this abrasive with the less expensive fused aluminas or with silicon carbide are used for specific purposes; for example, the latter blend can efficiently clean and grind castings having burned-on sand.

Trade Names: NZ Alundum, etc.

3.3. Sintered Aluminas

From Bauxite. Calcined bauxites are ground to a fine powder, mixed with an organic binder, such as grease, extruded through an orifice, cut, and fired statically or in a rotary furnace to temperatures between 1400 and 1600 °C [21]. This

results in limited recrystallization of the alumina, increased density, and great strength of the particles, which have the desired grain size without being crushed. The major use of this abrasive is the conditioning of stainless steel billets and slabs using hot-pressed resin-bonded wheels.

Trade Names: 76 Alundum, SO 200, etc.

From Alumina Gels. A colloidal dispersion of alumina monohydrate [*12252-67-4*] and of modifying oxides, such as zirconia and/or magnesia [*1309-48-4*], is formed, and the resulting gel dried to produce chunks. These are crushed and air fired (sintered) to above 1250 °C, resulting in considerable shrinkage and formation of a dense, sharp, and extremely tough abrasive [22], [23]. These expensive abrasives are now widely used in industry as they significantly outperform fused alumina grains for high-precision grinding and creep-feed grinding. They are mostly used in vitrified wheels, but specific operations requiring organic-bonded wheels, such as flute grinding, surfacing, and calibrating with disk grinders, also use sol – gel aluminas. Coated abrasives are also produced with these grains for foundry snagging with belts and fiber disks and for other work on stainless steel and high-resistance alloys. As new types of sol – gel aluminas are developed and production volume grows, they are progressively replacing fused aluminas in many operations.

Trade Names: Cubitron, SG, TG, etc. Often referred to with the generic name "ceramic abrasives".

3.4. Silicon Carbide

The discovery of silicon carbide [*409-21-2*] by Edward G. Acheson in 1891 was indeed epoch-making because it was the first synthetic abrasive invented and commercialized, and signaled the gradual decline in the use of natural abrasives (→ Silicon Carbide). In an attempt to make diamonds by an electric-arc heating process, Acheson produced a very few hard crystals. Knowing that they were not diamond but thinking that they were a combination of carbon and corundum, he called them "carborundum," a term that remained even after the crystals were determined to be silicon carbide. Carborundum became the name of the company he organized to exploit the discovery. Abrasive SiC is produced today in furnaces similar to the one he patented in 1893 [24]. Silica sand plus carbon in the form of coke, or low-ash coal in the approximate mass ratio of 60 : 40 is heated in a troughlike electric resistance furnace to produce SiC according to the equation:

$$SiO_2 + 3\,C \longrightarrow SiC + 2\,CO$$

Several grades of this abrasive are produced. The most common black or gray type is used in bonded and coated form for grinding low-tensile, nonferrous metals such as aluminum, brass, copper; some cast irons; and nonmetallics, such as glass, stone, concrete, ceramics, and refractories. A higher purity green variety is employed for those operations, such as rough grinding of cemented carbide tools with vitrified-bonded wheels, in which this abrasive's more friable characteristic and the light green color are helpful. A type lower in purity than that used for bonded and coated products has utility in loose-grain applications, such as wiresawing and lapping.

World production capacity for silicon carbide abrasives is listed in Table 2.

Table 2. World production capacity (10^3 t/a) for silicon carbide abrasives in 1996 and 1997 (estimated) [49]

Norway	80	80
Venezuela	40	40
Others	185	185
World total (rounded)	1100	1100

Trade Names: Carborundum, Crystolon, etc.

3.5. Boron Carbide

Abrasive boron carbide, B_4C [*12069-32-8*], is produced in electric resistance furnaces from a charge of high-purity boron oxide glass and high-purity coke according to the equation [25]:

$$2\,B_2O_3 + 7\,C \longrightarrow B_4C + 6\,CO$$

As explained in Section 5.3, this abrasive is unsuited for use in bonded or coated products. However, for loose-grain applications, such as the lapping of cemented carbides and other hard materials, it is used alone or mixed with silicon carbide.

Trade Names: Norbide, etc.

3.6. Diamond

Commercial availability of manufactured diamond [*7782-40-3*] is the most important abrasive development in the 20th century (→ Carbon). Not only did it eliminate occasional shortages of natural diamond grain, but also it made possible a great variety of diamonds with vastly different characteristics, thereby increasing diamond efficiency and consequent use.

Commercial manufacture of diamond requires high pressure (5.0 – 6.5 GPa) and high temperature (> 1400 °C) [26]. Depending upon manufacturing parameters, a wide range of properties may be obtained, from very friable composite structures of small diamond crystals to stronger single crystals containing various defects and inclusions, to very strong, almost flawless crystals, equidimensional in shape, with well-developed crystal faces. One leading producer offers no fewer than seven different basic types. Over the years the major manufacturers have gradually been able to produce economically high-quality single diamonds of larger and larger size, now up to 20 – 25 mesh (approximately 700 – 850 µm in diameter). No doubt they will continue to extend availability further in the coarse direction.

The two major producers further improved the efficiency of diamonds for use in resin-bonded products by introducing metal-clad varieties in 1966 [27]. These coatings are believed to improve wheel efficiency by controlling abrasive breakdown, and by acting as a heat sink between the abrasive and the bond, retarding deterioration of the latter from heat generated during grinding. The most commonly employed coatings are nickel-based (30, 55, or 60 wt %) or copper (50 wt %). Although used mostly with manufactured diamonds, the 55 % nickel coating is also available on natural diamonds.

World production of synthetic diamond is listed in Table 3.

In general, diamonds, both natural and manufactured, are used for lapping carbides and other hard materials, and for grinding, drilling, and sawing cemented carbides and a wide variety of nonmetallics, such as plastics, glass, stone, concrete, ceramics, refractories, and such electronic materials as silicon and quartz. Silicon carbide also can be used for these same materials. However, bonded diamond products, in spite of their higher cost, often are more efficient, resulting in lower total costs per unit of work performed. This is particularly true in cemented carbide grinding, where diamond, now nearly always one of the manufactured types, is used almost exclusively except for offhand roughing with vitrified-bonded green silicon carbide wheels. Because of the affinity between diamond (carbon) and iron, diamonds are not economical for grinding ferrous metals except those containing relatively large amounts of hard constituents, such as certain vanadium steels.

The cost of synthetic diamond has greatly decreased since the mid-1980s, and this has allowed it to be used in nonprecision applications such as cutting masonry materials, stones and bricks with steel disks on hand-held grinders. The disks have laser-welded, metal-bonded diamond segments, and their low cost and long life have allowed them to replace most conventional silicon carbide cutting-off disks.

3.7. Cubic Boron Nitride

The second, and eventually possibly the most important development in the abrasive area this century, was the invention [28] of cubic boron nitride (CBN) [*10043-11-5*], first introduced commercially in 1969 (→ Boron Carbide, Boron Nitride, and Metal Borides).

This abrasive may be made in any of the high-pressure, high-temperature apparatuses used for diamond production. By using different raw materials and manufacturing conditions, a variety of products having a range of friabilities may be produced. Color ranges from almost colorless through shades of yellow, red, and black. As with diamonds, the producers supply CBN in sized grains and flours. Metal cladding of this abrasive also has improved its efficiency in resin-bonded

products [29]. A 60 % nickel-based coating is used commonly.

Initial successful applications of CBN were for high-performance grinding of difficult to grind ferrous metals where use of fused alumina abrasives results in high rates of wheel wear per unit of material removed from the workpiece and in rapid dulling of the abrasive grains. Therefore machine productivity is low and grinding costs high, as is the liability of metallurgical damage to the work. Because of its hardness (inferior only to diamond), strength, low coefficient of friction during operation, and thermal and chemical stability to well over 1000 °C, CBN wheels, although expensive, increase productivity. This is because of much lower wheel wear, improved workpiece integrity, and fewer rejections and reworks. Now, with the development of computer-controlled, high-production systems especially designed for use with this abrasive, its application is being extended to more common, less difficult to grind ferrous metals. This has resulted in increased productivity for such operations as camshaft grinding in the automobile industry.

In 1981 one producer introduced a CBN family (*trade names:* Borazon 550, 560, 570) with sized grain that is polycrystalline and extremely tough. In certain applications resinoid- and vitrified-bonded wheels containing this abrasive have shown lower wheel wear than similar products containing the usual monocrystalline CBN. However, the expense of the abrasive has been a problem in establishing lower overall grinding costs in many cases.

Production of CBN by region is summarized in Table 4.

Table 4. Production of CBN by region (10^6 carat) [51]

Trade Names: Borazon, Amber Boron Nitride, etc.

4. Manufacture and Testing of Sized Grains

As mentioned in Chapter 3, some abrasive types are produced directly to size for use in bonded or on coated products. Other abrasives, such as the fused aluminum oxides, must be crushed, sized, and otherwise treated before use.

Crushing is accomplished by a variety of means, depending on the shape and other characteristics of the desired product. Jaw crushers, hammer mills, roll mills (in which precrushed crude is passed through sets of alloy steel rolls), and ball or rod mills commonly are employed. If exceptionally equidimensional particles are desired, the grain may be mulled by the use of heavy steel rollers working the grain in a revolving pan.

To produce specific grit sizes, screening is used for the coarser ones (macrogrits; >50 µm

Table 5. Standards for sizing of abrasive grains

Type of abrasive	Screen sizes (macrogrits)	Subsieve sizes (microgrits)
All except diamond and CBN for :		
Grinding wheel and general industrial usage	ANSI B74.12−1992 [30]	ANSI B74.10−1977 (R1992)
	FEPA 42/93	FEPA 42/93
	ISO 8486, part 1 (1996)	ISO 8486, part 2 (1996)
Coated Applications	ANSI B74.18−1996	ANSI B74.18−1996
	FEPA 43/93	FEPA 43/93
	ISO 6344, parts 1 and 2 (1998)	ISO 6344, part 3 (1998)
Diamond, CBN, all uses	ANSI B74.16−1995	ANSI B74.20−1997
	FEPA 61/97	FEPA 60/77 (under revision)

in diameter). Finer sizes (micogrits) are separated by various elutriation methods. Centrifuging often is employed for the finest grains.

For checking the sizing of abrasive grits, the standards shown in Table 5 are used.

Conventional (i.e., non-diamond and non-CBN) abrasive grits are sized according to standards that assign each size a number and define the mean size and the proportion and dimensions of coarser and finer sizes that can be present. The standards usually differ for bonded and coated abrasives, as the optimum performance of the products requires different grain shapes and a different size distribution for each grit number. For example, FEPA (Federation of European Producers of Abrasive Products) has issued two standards: FEPA 42/93, which defines the F series for bonded abrasives, and FEPA 43/93, which defines the P series for coated abrasives. Similarly, ISO has issued ISO 8486 for bonded and ISO 6344 for coated abrasives. The grit numbers and the mean particle sizes in micrometers in the F series (aluminum oxide and silicon carbide grains for grinding wheels and other bonded abrasives are as follows:

∗ The grit designation is prefixed with a "D" to denote diamond and a "B" to denote CBN.

Figure 1 shows the relationship between grit size designations, sieve numbers, aperture size of sieves, and micrometer dimensions of particles for both screen-size and subscreen-size grains according to FEPA standards [31].

In practice various manufacturers use other equipment for checking abrasive sizing, such as the Coulter counter.

The major suppliers of subsieve diamond and cubic boron nitride products offer their own series, many items of which are extremely well classified into the very narrow ranges demanded by the trade. One supplier, for example, offers 17 sizes from 40 – 80 µm down to 0 – 0.5 µm.

After sizing, grits are washed, processed further, and tested using the methods in Table 7.

Instrumental techniques such as atomic absorption, emission spectroscopy, and X-ray fluorescence are used in practice for chemical analyses. Eventually new standards based on such methods will be forthcoming.

Strength of abrasive grains containing glass as a minor impurity, as in regular fused alumina, can be increased significantly by heat treatment in air to 1250 – 1350 °C. The glass migrates to the surface, sealing microcracks, and thus repairing damage caused by the crushing operation. Alternatively, the grain may be coated with a glass frit that matures at 800 – 1000 °C. Such treatments increase abrasive efficiency in heavy-

Table 7. Test methods for abrasive grain properties

Application	Test method	Comments
Presence of magnetic particles	ANSI B74.19 – 1990 (R1995)	
Measure of coating weight for diamond and CBN grains	FEPA 62/93	
Relative strength of saw diamond grits	FEPA 63/93	
Degree of capillarity	ANSI B74.5 – 1964 (revised 1995)	capillarity is increased by heating to 500 – 600 °C
	ISO 9137 (1990)	used for conventional abrasives
	FEPA 44/93, part 3	used for conventional abrasives
Grain shape	ANSI B74.4 – 1992 (R1997)	equidimensional shapes pack to a higher bulk density than flat or slivery ones
	ANSI B74.17 – 1973 (revised 1993)	this method is used for testing diamond and CBN
Bulk density	ISO 9136, parts 1 and 2 (1989)	used for conventional abrasives
	FEPA 46/93, part 2	
Grain strength (friability)	ANSI B74.8 – 1987	ball mill test (see Section 5.2 for interpretation of strength data)
Chemical analysis (classical wet methods)	FEPA 46/93	used for fused aluminum oxides
	ISO 9285 (1995)	used for fused aluminum oxides
	ANSI B74.14 – 1992	used for fused aluminum oxides

	FEPA 45/93	used for silicon carbides
	ANSI B74.15 – 1992	used for silicon carbides
Sampling and splitting	ISO 9138 (1993)	used for conventional abrasives
	FEPA 44/93, part 1	used for conventional abrasives
Test-sieving machines	ISO 9284 (1992)	used for conventional abrasives

duty applications, such as in the conditioning of steel slabs and billets with resinoid wheels.

Sometimes grits are treated with a liquid silicone resin before being incorporated into resin-bonded products. Silicon carbide grain may be subjected to froth flotation to remove free carbon and/or treated with a sodium hydroxide solution to remove free silicon. In order to insure vitrified-bonded products free from iron spotting, fused alumina grains, especially the white variety, may be acid-treated to remove ferrosilicon or tramp steel not eliminated by magnetic separation.

5. Physical and Chemical Properties

5.1. Hardness

The hardness level required of an abrasive obviously depends upon the specific use. However, the vast majority of industrial applications necessitates abrasives at least as hard as quartz.

A common means for determining hardness is by use of the Knoop indenter, a gem-quality diamond carefully lapped to the shape of an elongated pyramid. This device indents the material to be tested under controlled-load conditions [32]. The applied gram load must be specified, e.g., K_{100}, because it can cause considerable variation in the resulting Knoop hardness number. Values of K_{100} for common abrasives compared with the Mohs' hardness scale generally used by mineralogists are:

	Knoop, K_{100}	Mohs'
Quartz (silica)	820	7
Spinel (magnesium aluminate)	1270	
Garnet (almandite from Adirondacks, U.S.)	1360	8
Fused zirconia-alumina (NZ Alundum type)	1600	
Fused alumina (white type)	2050	9
Silicon carbide	2480	
Boron carbide	2800	
Cubic boron nitride	4700	
Diamond	7000 – 8000	10

5.2. Grain Strength or Fracture Toughness

Strengths resulting from three different properties are important and usually act together during an abrasive operation. First is the grain shape, the blocky or equidimensional one being referred to as a strong shape, that with many flakes and slivers as a weak shape. Second, grains containing microcracks and other flaws produced by crushing tend to be weaker than those produced directly to size without subsequent comminution, assuming that the grains are otherwise of about the same overall shape. Third, is the intrinsic strength of the body of the abrasive itself.

Although this is difficult to measure in finished grain form because of the effect of shape and crushing, relative intrinsic strengths may be estimated. If the difference between abrasives is large, this is done by means of data derived from ball milling (method of ANSI B 74.8−1977) or by crushing or blasting tests, provided that the difference in grain shape has at least been minimized and crushing histories are similar.

The fracture strength or toughness of ceramics is determined by studying the cracking produced by indenting polished sections with a Vickers indenter. The load is such that fractures are produced at the corners of the indentations. The fracture toughness (K_c) may be calculated by measuring the average crack length and the diagonals of the indentations when Young's modulus and the microhardness are known [33]. This method of measuring intrinsic strength or toughness of abrasives is destined to replace the other procedures because it is a direct one.

5.3. Resistance to Attrition or Plastic Flow

When abrasive boron carbide was first produced in the early 1930s, its hardness was greater than that of any known material except diamond. Its effectiveness as an abrasive in loosegrain lapping operations, such as on cemented carbides, correlated well with relative hardnesses, being greatly superior to silicon carbide and fused aluminas, but inferior to diamond. For that reason boron carbide was excepted to have extensive applications in bonded products, replacing those older, softer abrasives. However, extensive grinding tests proved boron carbide to be completely unsuitable in any such operation because the wheels quickly became dull. The major reasons appear to be oxidation of the boron carbide, and the reaction or diffusion between the abrasive and the material being ground. A similar explanation appears to apply to the relatively poor performance of diamond when grinding common ferrous metals. Temperatures at the interface may approach the melting point of steel. Under these conditions both the abrasive and piece being worked are greatly softened, with reaction or diffusion between the two greatly accelerated. The result is attritious wear or plastic flow, leading to the development of polished flats on the abrasive grains and so the loss of much or all of their stock-removal capabilities [34–36].

For loose-grain lapping operations, hardness and strength are the most important abrasive properties. However, stock removal with fixed abrasives is a complicated process involving the interaction of hardness, strength, and chemical properties of both the abrasive and the workpiece. In addition the conditions of operation also must be considered.

6. Loose-Grain Applications

Blasting. In this operation, screen-size abrasives, such as quartz sand, garnet, fused alumina, and silicon carbide, impact the work material by means of compressed air, centrifugal force, or pressurized water. Blasting is used to descale or otherwise clean and deburr metal parts, clean buildings, and carve letters and designs on stone.

Wire Sawing. Endless, multistrand, twisted wire under tension is used to carry a slurry of water and abrasive for sawing blocks or slabs of stone such as limestone, marble, and granite. Quartz sand may be used to cut the softest stones, but fused alumina or silicon carbide is required for the harder granites and sandstones. This method is used both in the quarrying process itself and to shape and slice blocks removed from the quarry.

Barrel Finishing. Metal parts requiring cleaning, deburring, and/or refining of surface finish are tumbled in a slowly rotating barrel with water, acid or alkaline cleaning compounds, and suitable abrasives. Depending upon the work material and finishing requirements, the abrasives may be natural ones, such as emery or crushed granite, or, more commonly, manufactured abrasives, such as fused aluminas. The latter may be used as such, or they may be bonded with vitrified or organic materials into specific shapes, such as triangles, stars, or pins. A more efficient finishing method, involves vibrating the materials in bowls or tubs.

Lapping. Loose abrasives in a vehicle of water, soluble oil, kerosine, greases, etc., can be used to fine grind flat, cylindrical, or other surfaces. Laps of cast iron and other metals are used, and the abrasive grains may become embedded to some degree in these during the operation. The choice of abrasive depends upon the nature of

the workpiece. Harder abrasives, such as boron carbide and diamond, are most suitable for lapping cemented carbides, whereas quartz, garnet, and emery may be used on relatively soft materials. Gear lapping is accomplished by feeding an abrasive slurry between the parts as they revolve.

Buffing. Abrasives, such as fused aluminas and silicon carbide of subsieve size, are bonded with greases or waxes into cakes or sticks. These are applied dry to the face of rotating resilient wheels made of such materials as felt and other cloth types. The bond melts during the buffing operation so the abrasive is not fixed. A small amount of material is removed from the work, usually a metal; but, more importantly, a lustrous, satin, or mirror-like finish is produced.

7. Bonded Abrasive Products

These are rigid or only slightly flexible bodies, such as grinding wheels, which normally have more than a single layer of abrasive grains bonded with glass (vitrified bonds), organic materials, or metals. The products are manufactured in a wide variety of shapes and sizes, including wheels (mounted and unmounted), segments, bricks, sticks, etc. For details see ANSI B74.2–1974, Specifications for Shapes and Sizes of Grinding Wheels. . . . The specifications for diamond and CBN wheels are given in ANSI B74.3–1974 (revised 1980), and for marking of abrasive products in ANSI B 74.13–1977. Considering possible variations in types of abrasives, grit sizes, bond types, structure of the bodies (variations in volume percentages of abrasive, bond, and pores), and size and shape of the bodies themselves, it is understandable that major manufacturers produce several hundred thousand varieties of grinding wheels alone.

7.1. Vitrified Bonds

Abrasives bonded with glass include silicon carbide, diamond, cubic boron nitride, and all of the fused alumina types.

With fused alumina and silicon carbide, a typical manufacturing method involves coating the abrasive grain with premixed temporary and permanent bonding ingredients such as feldspar, clay, fluxes, or frits, molding the mix to a predetermined mass : volume ratio, drying it, altering the shape in the green state by shaving, if necessary, and finally maturing the bond by firing in a kiln, usually at 850 – 1250 °C or above. After it cools, a wheel may be sided and faced, and the hole reamed or bushed.

Products are characterized by volume percentages of abrasive, bond, and pores (Fig. 2). Softer grades contain higher pore volumes, and lower structure numbers have higher grain volumes. The final product is inspected by measuring mass : volume, modulus of elasticity, and resistance to penetration by a rotating chisel or by a blast of a known volume of sand or other abrasive under known pressure. The pores of the wheel may be filled with sulfur or waxes to improve grinding action by retarding loading of the wheel face with swarf during operation. A composite wheel can be made with a stronger center portion (finer grit abrasive, harder grade) to increase the overall strength of the body. Also the portion adjacent to the hole can be treated with a liquid epoxy resin for the same purpose.

Figure 2. Relationship of hardness to structure in bonded abrasives
Bv) Bond volume; Gv) Grain volume; Pv) Pore volume

Because of the high cost of diamond and cubic boron nitride (CBN), only a small portion of the body contains these abrasives, the remainder being the core or "preform". A "green" prepressed ceramic body is first formed, placed in

a mold, and the abrasive-bond mix packed between preform and mold assembly. Bonds commonly employed are of the borosilicate type from frits or raw materials of the same general composition. After pressing and stripping from the mold, the product is fired to 900 – 1000 °C. Because diamond oxidizes at such temperatures, firing is usually in nitrogen; CBN may be fired in air.

Content of diamond and CBN in bonded products is based on volume percentages, 100 concentration being 25 vol % and others being proportional. For diamond-containing items, concentrations are almost always in the range of 25 – 100, whereas for CBN the range is 50 – 200. Average porosities are lower and the items more durable than those containing fused aluminas and silicon carbide.

For the most part, vitrified bonds are used for precision operations, such as surface, internal, and cylindrical grinding, where close dimensional tolerances are required.

7.2. Organic Bonds

Phenol – Formaldehyde Polymers. Most organic bonds are of this type. They have gradually replaced vitrified types in rough grinding applications because the wheels are stronger and more shock resistant and so can be operated safely at higher speeds with resulting greater efficiency. Diamond and all of the manufactured abrasives described in Chapter 3 are available in this bond type.

For abrasives other than diamond and CBN, a common cold-pressed manufacturing method involves wetting the abrasive with furfural [*98-01-1*] or liquid phenolic resin followed by coating it with a premixed blend of powdered phenol – formaldehyde resin and fillers or grinding aids, such as pyrite (FeS_2), cryolite [*15096-52-3*], or potassium tetrafluoroborate [*14075-53-7*]. Molding is similar to that for vitrified products. Curing is carried out in an oven at 140 – 200 °C, or dielectrically. Very low porosity products may be produced by hot pressing at 160 – 175 °C followed by oven curing, as with the cold-pressed products.

When a softer grade action is desired, the phenolic resins may be modified with epoxies, rubbers, or other thermoplastics. Some resin-bonded products, such as thin wheels for cutting-off operations and portable wheels for offhand grinding, are reinforced by molding sheets of woven fiberglass onto the sides, within the body, or both.

Resin-bonded alumina and silicon carbide products are used for precision-grinding, roll-grinding, centerless-grinding, and, most commonly, for rough-grinding operations where dimensional tolerances and finish are less critical, as in offhand grinding of rough castings and the conditioning of steel billets and slabs.

Most diamond and CBN products are hot pressed, and preforms are employed, as with the vitrified-bonded analogs. Uses are mentioned in Sections 3.6 and 3.7.

Rubber. Natural or synthetic rubbers or combinations are milled between rolls to break down the fibers, after which the abrasive grain, fillers, and sulfur for vulcanization are added. After being mixed, the batch is calendered to the required thickness, cut to shape, and heated to 150 – 175 °C to vulcanize the rubber. Depending on the amount of sulfur, type of rubber, and variety and amount of fillers, the product may range from soft and resilient to hard.

Because of strength and resiliency, rubber cutoff wheels, particularly thin ones, give accurate cuts with good surface finish and little burring in wet-grinding operations. Another application is the grinding of ball bearing races and centerless feed wheels.

Shellac. Shellac is a natural polymer prepared by heating and filtering the secretion of the lac insect, a parasite found on tress in India and surrounding countries. A common wheel-making process involves coating the abrasive with shellac and hot pressing the mixture in steel molds. The mix also may be calendered into thin sheets, from which wheels are cut and cured at 150 – 175 °C. Another method involves moistening the abrasive with a shellac solvent, adding powdered shellac, mixing, cold pressing, and postcuring. Shellac wheels exhibit a considerable degree of thermoplasticity, giving rise to a soft grinding action with a distinct polishing characteristic. They are used in some wet, light grinding operations, particularly for finishing steel rolls.

Polyimide Polymers. For limited, specialized applications, such as the grinding of flutes on carbide drills, and edge-grinding of carbide inserts on certain types of machines, diamonds in a polyimide bond have proved to be advantageous [37]. This particular polymer has considerably higher resistance to thermal degradation than the phenol – formaldehydes.

7.3. Metal Bonds

The abrasive most often bonded with metal is manufactured diamond, but the use of cubic boron nitride (CBN) in metal bonds is expected to increase very significantly.

Three types of metal-bonded products are made:

1) Those in which the abrasive zone is bonded directly to the core by a heating process;
2) Those in which segments or rims are produced and then attached to the core or steel blade afterward;
3) Those bonded by electroplating.

For the first type, a core or preform is placed in a mold, and the abrasive-metal mix added and then pressed. After being stripped from the mold, the body usually is sintered to maximum density, or it may be sintered to controlled porosity followed by infiltration with a liquid metal, such as a silver solder. Alternatively, the product may be hot pressed in a graphite mold. Bond compositions vary greatly. Commonly used ones include bronzes, various cobalt and nickel alloys, steels, and cemented carbides. Maturing temperatures vary from 500 °C for bronzes to 1200 °C for cemented carbides. Firing is in neutral or reducing atmospheres. In general softer bonds are used with hard, dense work materials, whereas harder ones are used to grind relatively soft but abrasive materials. For example, bronze bonds commonly are used on dense alumina, cemented carbides, and quartz crystals, whereas carbide bonds often are used to groove concrete highways and cut sandstones.

In the case of rims and segments, similar bonds, manufacturing methods, and firing temperatures are employed. In the production of diamond blades for use in the construction industry, segments have been attached to the steel center by brazing. However, laser welding, introduced in 1982, has permitted a much higher bonding strength, virtually eliminating loss of segments because of weakening of the joint from the heat generated during the cutting operations.

Electroplated products normally have a rigid core, a nickel bond, and a single layer of either diamond or CBN. Examples are: diamond-coated mounted points and discs used by dentists, relatively inexpensive diamond-coated wheels for offhand sharpening of carbide tools, and wheels of complicated shapes coated with diamond or CBN used for form grinding of workpieces, where great precision can be attained because of little or no tool wear.

8. Coated Abrasive Products

In coated abrasives a single layer of abrasive grains is bonded with an adhesive to flexible or semirigid backings.

8.1. Components

Abrasives include quartz, known in the trade as flint; garnet; emery, usually the Turkish variety; fused aluminas of the regular, semifriable, white, and pink types; sintered aluminas made from gels; fused zirconia – alumina of the NZ Alundum variety; silicon carbide, black and green types; and diamond and CBN, for very limited applications.

Backings include *Paper* of different weights: A for fine hand sanding with sheets, C for medium hand operations or machine finishing, E for heavy machine grinding.

Cloth: woven cotton or polyester, stitch-bonded polyester. They must be specially treated before being coated with abrasives on cloth-finishing lines to give them the appropriate mechanical characteristics. Different weights are used, depending on the operation: J for flexible products, X or Y for coarse grits or use on powerful machines.

Combinations of paper plus cloth: used when limited backing stretching and high resistance to tearing are necessary: wide belts for high power machines, drum sanders.

Vulcanized fiber made of several layers of cotton-based paper gelatinized with zinc chloride and vulcanized together. Different thicknesses are used, from 0.4 to 0.75 mm, depending upon the required stiffness and strength. Main use is fiber disks for portable machines for rough grinding and semi-finishing.

Polyester films for microfinishing and polishing of mechanical, electronic and optic components with very fine P series grits and micron or sub-micron sizes Abrasive grains are aluminium oxide, silicon carbide, diamond and special materials such as alumina flour and chromium, iron, and cerium oxides.

Adhesives used are high-quality hide glue; phenol – or urea – formaldehyde resins; and polyurethane or epoxy-based varnishes. These adhesives may contain mineral fillers to modify the physical properties of the bond, or to aid the operations in other ways (see Section 7.2).

8.2. Production

A strip of backing material up to 1.5 m or more in width is passed into a making machine where a thin film of bond, known as the maker coat, is applied. Sized abrasive is fed onto it by gravity, or an electrostatic field is used to orient the longer dimension of the grain perpendicular to the backing. The coating may be closed, in which the abrasive entirely covers the adhesive, or open, in which 50 – 75 % of the surface is covered. The item is dried at about 60 °C after which another layer of adhesive, known as the sizing coat, is applied to secure more firmly the abrasive grains. This second coat may be of the same composition as the first, or it may be different, e.g., resin used over glue. Then the bond is dried further and cured at about 150 °C. The coated abrasive is then coiled into a large roll known as a jumbo.

For most uses a further operation is required to improve product flexibility. This involves breaking the bond in a controlled manner. In single flexing, cracks are developed at right angles to the length of the strip. In double flexing, there are two series of cracks at about 45° to the length. Triple flexing is a combination of the other two types. Because of disturbance to the abrasive bond layer by such operations, only the minimum amount needed to satisfy end-use conditions is employed.

8.3. Applications

The jumbo rolls are cut and converted into many different shapes: narrow rolls, sheets, disks, endless belts 10 to 3000 mm wide and 250 to 7000 mm long, flap wheels and flap disks, spirally wound cones and pencils. These shapes are used by hand or on sanding machines in practically all industries for roughing, finishing, and polishing of wood, sheet and structural metal, mechanical parts, weldings, lacquers, glass, plastic, rubber, plaster, semiconductors, etc.

9. International Quality Specifications

Because of the mature nature of the abrasive industry and the use of various specifications, truly international standards have been slow in developing.

However, the International Organization for Standardization (ISO) has been active in establishing specifications relating to bonded and coated products, and, to a lesser extent, to the abrasive grain itself. This organization has issued ISO standards, some 21 of which relate to those items [38]. Eleven of them cover designations and dimensions of various coated products, nine of bonded items, including diamond and CBN, and one relates to grit sizes of diamond and CBN.

National standards exist in the United States (ANSI) [30], Japan, Japanese Industrial Standards (JIS) [42], and Europe (FEPA) [31].

10. Safety

Bonded abrasive products are not indestructible. Strengths vary with such factors as the type of bond, the grit size of the abrasive, and the structure and grade of the product required to efficiently perform a particular grinding operation. Therefore, the user must take special precautions to see that these products are properly handled,

mounted correctly on the machine, and not operated at excessive speed. The latter is the most frequent cause of wheel breakage, leading to damage of equipment and possible personal injury. Most wheels are marked for maximum operating speeds or instructions are packaged with the items.

"Safety Requirements for the Use, Care and Protection of Abrasive Wheels," ANSI B 7.1–1988, 106 p., is particularly useful because it includes sections on definitions of the various types of grinding operations, and on wheel shapes with their limitations, and handling and storage of abrasive products. General conditions of machines, safety guards, flanges, proper methods for mounting, general operating rules, and, most importantly, standard and special maximum operating speeds are covered also.

"Safety Requirements for the Construction, Care and Use of Grinding Machines," ANSI B11.9–1975, 71 p., is likewise helpful because it contains sections on design of machines, guards and flanges; on operating risks, and on the responsibilities of manufacturer, employer, and employee in connection with the care and use of equipment.

An EC standard concerning the safety of grinding machines is in preparation (EN 13218).

Japanese Industrial Standards (JIS), R6240–1972 and R6241–1972 [42], as well as the European Safety Code, FEPA standard 12/87, are similar to ANSI B7.1 but vary in details. Requirements in Germany (VBG 49) are more stringent than in most other countries because high-speed wheels must carry a certificate with certifying that they have been tested by the manufacturer in accordance with the specifics of ZH 1/670. Independent tests also are carried out to assure compliance with ZH 1/670.

EC standards concerning the safety of bonded, coated, and diamond/CBN abrasives are in preparation [52].

Another potential risk involves the effect of breathing dusts generated during abrasive operations, such as grinding and polishing or blasting, particularly when done in a dry operation.

"Ventilation Control of Grinding, Polishing and Buffing Operations," ANSI Z 43.1–1966, 21 p., is of particular interest because it covers exhaust hoods and enclosures, with minimum exhaust volumes specified for various operations and wheel dimensions. Drawings of suitable equipment are included. Similarly, "Ventilation and Safe Practices of Abrasive Blasting Operations," ANSI Z9.4–1979, 12 p., includes sections on dust risks, equipment, and operational procedures. It contains information on minimum air volumes for blast cleaning rooms occupied by blasters.

Most abrasive products are inert, producing dusts classified as inert or nuisance types when the work material also is inert. When the dust is not inert, not only must the amount to which the operator is exposed be known, but also its composition. Most of the dust generated from dry grinding and coated-abrasive operations is from the work material, with lesser amounts derived from the abrasive products themselves. Some abrasive products incorporate active fillers or grinding aids containing sulfur or fluorine compounds. Use of coated abrasives containing quartz (free silica) as the abrasive may require special controls. Only when both the amount and the composition of the airborne dust are known can a determination be made as to whether the requirements of the particular jurisdiction (city, country, etc.) are being met, and the health of the operator safeguarded.

For further details see "Fundamentals of Industrial Hygiene" [43], which relates specifically to requirements in the United States but which should be of interest worldwide. Particularly valuable are the appendices and their revisions [44–47]. For requirements in Europe (MAK), see [48].

With respect to disposal of wastes from abrasive products, the major concern is related to the chemical composition of the swarf because of its finely divided nature and consequently large surface area, which accelerates solubility and chemical reactions. Because most of the grinding debris originates from the work material, primary interest resides in its composition, solubility, and toxicity, with secondary emphasis on those properties of the bonded or coated abrasive used in the operation. Knowledge of such factors is required to determine the method of disposal that will not have an adverse impact on the environment.

Disposal of organic-bonded wheels and coated abrasives is also becoming a problem as they release phenol when leached by rain water in open landfills.

1. Phytophagous Mites and Their Control

Mites belong to the phylum Arthropoda, the class Arachnida, and the order Acarina. They have developed an astonishing variety of feeding habits. Some mites are predators, while others feed on detritus in soil or water. The economically important species are parasitic on either animals (e.g., ticks, scab mites) or plants (e.g., spider mites, eriophyid mites). Phytophagous mites are found in all parts of the world on practically all crop plants and may cause considerable damage. Approximately 8 – 10 % (annually ca. $ 400 × 10^6) of the total insecticide-acaricide market is spent on the control of phytophagous mites.

1.1. Possible Reasons for the Mite Problem

In recent decades, attacks by mites on food crops and fibers have increased so drastically that in many situations mite control has become an important feature of crop protection. Reasons for this increase of mites are manifold and not yet completely understood. Intensified agricultural production methods, such as monocultures, extensive use of fertilizers, improved irrigation systems, and cultural practices such as pruning have improved the vigor and nutritional value of the plants. However, these conditions also are beneficial to the development of phytophagous mites and may result in higher rates of reproduction. Furthermore, the indiscriminate use of pesticides in the past may have reduced or even eliminated the populations of natural enemies of the mites (predatory mites and beneficial insects) thereby encouraging the development of certain phytophagous mite species. In addition, some insecticides (e.g., DDT, Carbaryl) used for the control of insect pests, may promote the reproduction of phytophagous mites [6–8].

1.2. Mite Species of Economic Importance

The economically important species of the phytophagous mites are as follows:

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a01_017

Tetranychidae – Spider mites

Tetranychus urticae (Koch), Two-spotted mite, widespread on fruit and on grapes, vegetables, cotton, hops, roses, ornamentals, and greenhouse cultures.

Tetranychus cinnabarinus (Boisduval), carmine mite, widely spread in the warmer climatic regions on cotton, fruit cultures, ornamentals, and in greenhouses.

Tetranychus kanzawai (Kishida), tea red spider mite, found on tea in Asia.

Tetranychus mcdanieli (McGregor), McDaniel mite, found on fruit on the west coast of the United States, as are other, different *Tetranychus* species.

Panonychus ulmi (Koch), European red mite, widespread on fruit (apples, peaches, pears, prunes, plums) and on grapes.

Panonychus citri (McGregor), citrus red mite, found in citrus cultures worldwide.

Tenuipalpidae – False spider mites

Various *Brevipalpus* species, flat mites, found on citrus and different subtropical fruits, tea, greenhouse cultures.

Tarsonemidae – Soft-bodied mites

Hemitaronemus latus (Banks), citrus silver mite, found on cotton, citrus, attacks a wide range of agricultural crops and ornamental and indigenous plants in tropical and subtropical regions.

Eriophyidae – Gall mites

Phyllocoptruta oleivora (Ashmead), citrus rust mite, found on citrus.

Aceria sheldoni (Ewing), citrus bud mite, found on citrus.

Life cycles and behavioral and morphologic characteristics of mites vary greatly. The description of life history given here concentrates on the agriculturally important Tetranychidae family.

The *spider mites* are 0.3 – 0.5 mm long, eggshaped, eight-legged animals covered with hairlike appendages. These hairs (setae) are immobile and are sense organs. Spider mites live in dense colonies, mainly on the underside of the leaves. In such colonies, usually all the development stages are present: eggs, larvae, and nymphs, as well as adults of both sexes.

Many spider mite species produce protective webbing composed of almost invisible strands of silk; these webs produce a favorable microclimate on the leaf surface. Characteristic of spider mites is their enormous reproductive potential: a female of the European red mite (*Panonychus ulmi*) produces 14 – 30 eggs during its lifetime, the female two-spotted mite as many as 70 – 120. The tiny, pale green eggs are usually deposited on the underside of the leaves within the webbing [9–11].

The eggs hatch after 3 – 4 days in the case of *Tetranychus* species, whereas in the European red mites the first instar larva appears after 6 – 20 days. All the spider mites go through five stages in their life cycle: egg, six-legged larva, eight-legged protonymph, deutonymph, and adult. These stages are separated by resting stages followed by molts. The time for the whole development depends strongly upon the temperature, humidity, and the host plant. Under favorable conditions, the postembryonal development in Tetranychidae is completed within 8 – 14 days.

Orchard mites usually develop six to eight generations per season, depending on the areas where they occur. In greenhouses and in warm climates, the two-spotted mite may develop up to 30 generations per vegetation period, whereas for *Panonychus* species only 6 – 20 generations can be expected.

The climatic conditions during the summer months have a strong influence on the population build-up during the following spring. Most spider mites overwinter as bright orange adult females within bark crevices or in plant debris on the ground. The European red mite is an exception, overwintering as a winter egg on twigs.

Many weed species are excellent host plants from which the spider mites may move on to crop plants, either by crawling or by ballooning (transport by wind). All mites live on the sap of the plant, piercing the leaf tissue with the two sharp lances attached to the mouth and thus puncturing the cells in the leaf epidermis. The leaves then become speckled, later turn brown, and, if the attack is severe, may drop. As a consequence, photosynthesis and respiration are impaired and this may affect the number of flower buds in the following season. A mass attack of phytophagous mites on deciduous fruit may result in yield losses of up to 40 % [12].

The *gall mites* (Eriophyidae) are very tiny rodshaped mites with threadlike appendages. Gall mites are very host specific and have high reproductive potential. They destroy buds,

leaves, and fruit, and they also transmit viruses. They may cause serious economic damage, especially in citrus fruits.

After a heavy attack of citrus rust mites (*Phyllocoptruta oleivora*), the fruit turns reddish brown and shrinks because of the loss of water. The citrus bud mite (*Aceria sheldoni*) causes malformation of citrus fruits.

1.3. Possibilities for Mite Control

Chemical treatment can be aimed either at overwintering eggs (e.g., those of *Panonychus ulmi*) or at the mobile stages of the mites. Winter eggs often are treated with mineral oils. For the effective control of mites during the vegetative period, a number of chemicals are available. However, compounds that are effective against all development stages and have a long-term residual effect are preferred.

The compounds used should be well tolerated by the plants, and the effects on environment and beneficial insects should be minimal. The population of these natural enemies, which could control mite populations effectively, has been reduced severely or eliminated in most orchards, vineyards, and citrus groves as a result of the use of broadspectrum pesticides aimed at targets other than mites.

Biological control of phytophagous mites by releasing their natural enemies, such as predatory bugs or coccinellids, has been successful in greenhouses or in plastic tunnels. However, only limited success has been achieved under field conditions [13–15].

Integrated pest management, which makes use of a variety of possible techniques, including chemicals, to keep the pest population below the economic threshold, is far more promising than simple biological control. In integrated pest management systems, chemicals are used only when the population density reaches a certain level (economic threshold) and if possible, selective acaricides are chosen so as not to harm beneficial insects and predatory mites.

1.4. Mite Resistance

In many areas, mites have developed resistance to certain chemicals: their control therefore has become problematic. Because of the large number of generations per season, selection may occur very rapidly in a mite population. Resistance is induced by repeated application of the same or closely related chemicals. To compensate for this effect, higher dosages are needed, but this is not a long-term solution to the resistance problem. New compounds with new modes of action must continue to be developed to replace the older ones, that have decreased in effectiveness.

New control concepts, such as integrated pest management, have made it possible to reduce the number of acaricide treatments in many situations, and this has slowed development of resistance in mite populations.

2. Older Acaricides

Products introduced at the beginning of the pesticide era still find limited use as acaricides in various parts of the world.

Nitrophenols , in combination with mineral oil, were used to fight mites in orchards by eliminating their overwintering eggs. However, the phytotoxicity of these compounds has been a drawback [16, p. 527]. For a review of nitrophenols with acaricidal activity see [17, p. 2] and [18, p. 537].

Sulfur [*7704-34-9*], used mainly as a protective fungicide to control powdery mildews, is effective against the mobile stages of various mite species. It is used in combination with other fungicides and insecticides mainly in vineyards [17, p. 2].

Azobenzene [*103-33-3*] has been used as a fumigant in greenhouses against insects and mites, especially against eggs [17, p. 2].

Binaparcryl [*485-31-4*] has been used as a nonsystemic acaricide, mainly against all stages of spider mites and powdery mildew of apples, citrus fruits, cotton, etc. [19, p. 73].

Chlorfenson [*80-33-1*] has been used as a nonsystemic acaricide with long residual ovicidal activity. It is effective against mites of citrus and other fruits [19, p. 150].

Tetrasul [*2227-13-6*] has been used as a nonsystemic acaricide, particularly suitable for the control of various phytophagous mites which hibernate in winter egg form. It has been used on vegetables and fruits [19, p. 790].

Chlorpropylate [*5836-10-2*] has been used as a nonsystemic contact acaricide on cotton, fruits, and ornamentals [19, p. 169].

Aldoxycarb [*1646-88-4*] is a systemic insecticide and nematicide, and is a potent cholinesterase inhibitor. It has been used on tobacco and as a cotton seed dressing [19, p. 9].

Chlorobenzilate [*510-15-6*] is a nonsystemic acaricide with little insecticidal activity. It has been used against phytophagous mites on fruits and vegetables [19, p. 162].

3. Insecticides with Acaricidal Activity

3.1. Organophosphates and (Oxime)Carbamates

Organophosphates and carbamates, used as broad-spectrum insecticides but also exhibiting acaricidal action, were able to contain the mite problem for some time. However, development of mite resistance toward these compounds has made them less and less effective as acaricides.

Aldicarb [*116-06-3*], 2-methyl-2-(methylthio)propanal *O*-methylcarbamoyloxime, $C_7H_{14}N_2O_2S$, M_r 190.3, *mp* 98 – 100 °C, forms colorless crystals which are practically insoluble in heptane and mineral oils, moderately soluble in water, and soluble in most organic solvents [20, p. 26].

Aldicarb is produced by reaction of isobutene with nitrosyl chloride followed by reaction of the product with sodium methyl sulfide; the resulting oxime is then converted into the carbamate with methyl isocyanate [21].

Aldicarb (announced in 1965) is a cholinesterase inhibitor which is metabolically activated to sulfoxide. It is applied to soil to control chewing and sucking insects, spider mites, and nematodes in glasshouse and outdoor ornamentals, vegetables, sugar beet, peanuts, fruits, etc.

Trade Names. Temik (Rhône-Poulenc); Sanacarb (Sanachem).

Chlorfenvinphos [*470-90-6*], 2-chloro-1-(2,4-dichlorophenyl)vinyl diethyl phosphate, $C_{12}H_{14}Cl_3O_4P$, M_r 359.6, *mp* – 23 to – 29 °C, *bp* 167 – 170 °C, is a colorless liquid which is sparingly soluble in water, and miscible with most organic solvents [20, p. 211].

(*Z*) (*E*)

Chlorfenvinphos is produced by reaction of 2,4-dichloroacetophenone with triethyl phosphite [22].

Chlorfenvinphos (announced in 1952) is used for soil application to control root flies, root worms, and insects in vegetables and fruit flies in maize.

Trade Names. Birlane (Cyanamid); Apachlor (Rhône-Poulenc).

Chlorpyrifos-methyl [*5598-13-0*], *O,O*-dimethyl *O*-3,5,6-trichloro-2-pyridyl phosphorothioate, $C_7H_7C_{13}NO_3PS$, M_r 322.5, *mp* 45.5 – 46.5 °C, consists of colorless crystals which are sparingly soluble in water but soluble in acetone, benzene, chloroform, hexane, and methanol [20, p. 237].

Chlorpyrifos-methyl is produced by reaction of 3,5,6-trichloro-2-pyridinol with dimethylthiophosphoryl chloride [23].

Chlorpyrifos-methyl is used to control aquatic larvae, flies, household pests, mosquitoes, pests in stored grain, and various foliar crop pests.

Trade Name. Reldan (DowElanco); Pyriban (Aimco).

Diazinon [*333-41-5*], *O,O*-diethyl *O*-2-isoproyl-6-methylpyrimidine-4-yl phosphorothioate, $C_{12}H_{21}N_2O_3PS$, M_r 304.3, *bp*

83 – 84 °C (26.6 mPa), is a clear colorless liquid which is sparingly soluble in water but completely miscible with common organic solvents [20, p. 354].

Diazinon is produced by condensation of isobutyramidine with acetoacetate to yield the intermediate 2-isopropyl-4-methylpyrimidine, which is transformed into the final product by treatment with diethylthiophosphoric acid [24].

Diazinon (announced in 1953) is a nonsystemic insecticide/acaricide with contact, stomach, and respiratory action. It is used to control sucking and chewing insects and mites on a variety of crops.

Trade Names. Basudin (Novartis); Dianon (Nippon Kayaku); Knox-out (Elf Atochem).

Dicrotophos [*141-66-2*], dimethyl (*E*)-2-dimethylcarbamoyl-1-methylvinyl phosphate, $C_8H_{16}NO_5P$, M_r 237.2, *bp* 460 °C, is a yellowish liquid which is completely miscible with water and common organic solvents [20, p. 382].

(*E*)

Dicrotophos is produced by reaction of trimethyl phosphite with 2-chloro-*N,N*-dimethyl-3-oxobutyramide [25].

Dicrotophos (announced in 1965) is used to control sucking, chewing, and boring insects and mites in cotton, coffee, rice, sugar cane, and tobacco.

Trade Names. Bidrin (Cyanamid); Dicron (Hui Kwang).

Dimethoate [*60-51-5*], *O,O*-dimethyl *S*-(*N*-methylcarbamoyl)methyl phosphorodithioate, $C_5H_{12}NO_3PS_2$, M_r 229.2, *mp* 51 – 52 °C, consists of colorless crystals which are moderately soluble in water, soluble in alcohols, benzene, chloroform, dichloromethane, ketones, and toluene [20, p. 550].

Dimethoate is produced by reaction of the sodium salt of *O,O*-dimethyldithiophosphoric acid with *N*-methylchloroacetamide [26].

Dimethoate (announced in 1948) is effective against houseflies and Diptera of medical importance.

Trade Names. Cygon, Roxion (Wilbur-Ellis); Perfekthion (BASF); Champ (Searle India); Danadim (Cheminova); Robgor (Ramcides).

Disulfoton [*298-04-4*], *O,O*-diethyl *S*-(2-ethylthio)ethyl phosphorodithioate, $C_8H_{19}O_2PS_3$, M_r 274.4, *mp* < −25, *bp* 128 °C, is a colorless oil which is sparingly soluble in water but readily miscible with common organic solvents [20, p. 438].

Disulfoton is produced by reaction of the sodium salt of diethyldithiophosphoric acid with ethylmercaptoethyl chloride [27].

Disulfoton (announced in 1952) is used to control aphids, thrips, mealybugs, other sucking insects, and spider mites in potatoes, vegetables, cereals and other crops.

Trade Names. Disyston (Bayer); Solvirex, Fremin AL (Novartis).

EPN [*2104-64-5*], *O*-ethyl *O*-4-nitrophenyl phenylphosphonothioate, $C_{14}H_{14}NO_4PS$, M_r 323.3, *mp* 34.5 °C, consists of yellow crystals which are practically insoluble in water but soluble in common organic solvents [20, p. 464].

EPN is produced by reaction of benzene with phosphorus trichloride in the presence of aluminum chloride and treatment of the resulting

product with phosphenyl chloride to give the thiophosphonic acid, which is converted to ethyl phenyl thiophosphonate chloride by treatment with ethanol, followed by condensation of the product with the sodium salt of *p*-nitrophenol [28].

EPN (announced in 1948) is used against a broad range of Lepidoptera larvae, especially ballworms and *Alabama argillacea* in cotton, *Chilo* spp. in rice, and other leaf-eating larvae in fruit and vegetables.
Trade Name. EPN (Nisson).

Ethion [*563-12-2*], *O,O,O′,O′*-tetraethyl *S,S′*-methylene bis(phosphorodithioate), $C_9H_{22}O_4P_2S_4$, M_r 384.5, *bp* 164–165 °C (40 Pa), is a colorless to amber liquid which is practically insoluble in water but miscible with most common organic solvents [20, p. 480].

Ethion is produced by reaction of diethyldithiophosphoric acid with formaldehyde in the presence of sulfuric acid [29].

Ethion (announced in 1957) is used to control spider mites, aphids, scale insects, thrips, and lepidopterous larvae in fruits, vegetables, and turf.
Trade Names. Ethiol, Rhodocide (Rhône-Poulenc); Tafethion (Rallis); Dhanumix (Dhanuka).

Fenothiocarb [*62850-32-2*], *S*-4-phenoxybutyl dimethylthiocarbamate, $C_{13}H_{19}NO_2S$, M_r 253.4, *mp* 40–41 °C, consists of colorless crystals which are sparingly soluble in water but readily soluble in cyclohexanone, acetonitrile, acetone, xylene, methanol, and hexane [20, p. 517].

Fenothiocarb is produced by reaction of the sodium salt of *N,N*-dimethylcarbamothioate with phenoxybutylchloride, which is obtained by reaction of an excess of dichlorobutane with phenol in the presence of potassium hydroxide [30].

Fenothiocarb (announced in 1985) is a nonsystemic acaricide used to control eggs and young stages of *Panonychus citri*, *Panonychus ulmi*, and other *Panonychus* spp.
Trade Name. Panocan (Kumiai).

Formothion [*2540-82-1*], *O,O*-dimethyl *S*-[formyl(methyl)carbomylmethyl] phosphorodithioate, $C_6H_{12}NO_4PS_2$, M_r 257.3, *mp* 25–26 °C, is a pale yellow viscous liquid or crystalline mass which is moderately soluble in water but completely miscible with common organic solvents [20, p. 625].

Formothion is produced by reaction of the sodium salt of *O,O*-dimethyldithiophosphoric acid with *N*-methyl *N*-formyl carbamoylmethyl chloride [31].

Formothion (announced in 1960) is used against a wide range of sucking and mining insects, such as Aphididae, bugs, Cicadellidae, Cocidae, as well as against some chewing insects and spider mites on a variety of field crops, fruit trees, citrus and other tropical fruit, cotton, ornamentals, rice, tobacco, and vegetables.
Trade Name. Anthio (Novartis).

Mecarbam [*2595-54-2*], *O,O*-diethyl *S*-(*N*-ethoxycarbonyl-*N*-methylcarbamoylmethyl) phosphorodithioate, $C_{10}H_{20}NO_5PS_2$, M_r 329.4, *bp* 144 °C (2.7 Pa), is a pale yellow to brown oil which is sparingly soluble in water, soluble in aliphatic hydrocarbons, and miscible with alcohols, esters, and ketones [20, p. 774].

Mecarbam is produced by reaction of the sodium salt of *O,O*-diethyldithiophosphoric acid with *N*-ethoxycarbonyl-*N*-methylcarbamoylmethyl chloride [32].

Mecarbam (announced in 1961) possesses slight systemic properties, contact and stomach action, and long residual activity. It is used to control aphids, suckers, whitefly, scale insects, mealybugs and red spider mites on a variety of crops; and leaf hoppers, plant hoppers, and miners on rice.
Trade Name. Murfatox (Efthymiadis).

Methacrifos [*62610-77-9*], (*E*)-*O*-2-methoxycarbonylprop-1-enyl *O,O*-dimethyl phosphorothioate, $C_7H_{13}O_5PS$, M_r 240.2, *bp* 90 °C (1.3 Pa), is a colorless liquid which is sparingly soluble in water and miscible with many organic solvents [20, p. 806].

Methacrifos is produced by reaction of 2-hydroxymethylenepropionic acid methyl ester with dimethylthiophosphoryl chloride [33].

Methacrifos (announced in 1977) is an insecticide and acaricide with respiratory, contact, and stomach action. It is used for control of arthropod pests in stored products by incorporation or by surface treatment.
Trade Name. Damfin (Novartis).

Methamidophos [*10265-92-6*], *O,S*-dimethylphosporamidothioate, $C_2H_8NO_2PS$, M_r 141.1, *mp* 44.9 °C, consists of colorless crystals which are highly soluble in water, isopropanol, and dichloromethane, and moderately soluble in hexane and toluene [20, p. 808].

Methamidophos is prepared by isomerization of *O,O*-dimethylthiophosphamidate [34].

Methamidophos (announced in 1970) is a systemic insecticide and acaricide with contact and stomach action. It is used for control of chewing and sucking insects and spider mites on ornamentals, vegetables, and fruits.
Trade Names. Monitor (Bayer, Tomen, Valent); Tamaron (Bayer); Metaphos (Eftymiadis); Patrole (Pruductos OSA).

Methidathion [*950-37-8*], *O,O*-dimethyl *S*-2,3-dihydro-5-methoxy-2-oxo-1,3,4-thiadiazol-yl methyl phosphorodithioate, $C_6H_{11}N_2O_4PS_3$, M_r 302.3, *mp* 39 – 40 °C, consists of colorless crystals which are sparingly soluble in water, moderately soluble in hexane and *n*-octanol, and soluble in ethanol, acetone, and toluene [20, p. 811].

Methidathion is produced by reaction of 2-methoxy-1,3,4-thiadiazol-5(4*H*)-one with dimethyldithiophosphoric acid via the *N*-chloromethyl derivative or in a one-step reaction in the presence of formaldehyde [35].

Methidathion (announced in 1965) is a non-systemic insecticide and acaricide with contact and stomach action that is used against a wide range of sucking and chewing insects and spider mites in many crops.
Trade Names. Supracide (Novartis); Suprathion (Makhteshim-Agan).

Methiocarb [*2032-65-7*], (3,5-dimethyl-4-methylthio)phenyl methylcarbamate, $C_{11}H_{25}NO_2S$, M_r 225.3, *mp* 119 °C, consists of colorless crystals which are sparingly soluble in water, moderately soluble in hexane, and soluble in dichloromethane and isopropanol [20, p. 813].

Methiocarb is produced by reaction of 4-methyl-3,5-dimethylphenol with chloroacetoacetate [36].

Methiocarb (announced in 1962) is used for control of slugs and snails in a wide range of agricultural applications: broad-range control of Lipidoptera, Coleoptera, Piptera, Thysanoptera, and Homoptera in vegetables, fruits, oilseed rape, and ornamentals.

Trade Names. Draza, Mesurol (Bayer).

Methomyl [*16752-77-5*], *S*-methyl-*N*-(methylcarbamoyloxy) thioacetimidate, $C_5H_{10}N_2O_2S$, M_r 162.2, *mp* 78 – 79 °C, consists of colorless crystals which are fairly soluble in water and highly soluble in methanol, ethanol, acetone, isopropanol [20, p. 815].

Methomyl is produced by chlorination of acetaldoxime and conversion of the resulting α-chlorooxime with sodium methylmercaptide [37].

Methomyl (announced in 1968) controls a wide range of insects and spider mites in fruits, vines, olives, hops, vegetables, and ornamentals.
Trade Names. Lannate (Du Pont); Methavin (Rhône-Poulenc); Methosan (Sanachem); Nudrin (Cyanamid).

Mevinphos [*26718-65-0*], 2-methoxycarbonyl-1-methylvinyl dimethyl phosphate, $C_7H_{13}O_6P$, M_r 224.1, *bp* 21 °C (*E* isomer), 6.9 °C (*Z* isomer), is a colorless liquid which is completely miscible with water and many organic solvents [20, p. 844].

(*Z*)

(*E*)

Mevinphos is produced by reaction of trimethyl phosphite with chloroacetoacetate [38].

Mevinphos (announced in 1953) is used for control of chewing and sucking insects and spiter mites on a wide range of crops.
Trade Names. Phosdrin (Cyanamid, Amvac); Duraphos (Amvac); Mevindrin (Hui Kwang).

Monocrotophos [*2157-98-4*], dimethyl (*E*)-1-methyl-2-(methylcarbamoyl)vinyl phosphate, $C_7H_{14}NO_5P$, M_r 223.2, *mp* 54 – 55 °C, consists of colorless, hygroscopic crystals which are soluble in water, methanol, acetone, and *n*-octanol [20, p. 849].

Monocrotophos is produced by reaction of trimethylphosphite with chloroacetoacetic acid methylamide in the presence of a base [39].

Monocrotophos (announced in 1959) is used for control of a wide range of pests on cotton, rice, maize, vegetables, and ornamentals.
Trade Names. Azodrin (Cyanamid); Nuvacron (Novartis); Apadrin (Rhône-Poulenc); Balwan (Rallis); Monodhan (Dhanuka).

Omethoate [*1113-02-6*], *O,O*-dimethyl *S*-methylcarbamoylmethyl phosphorothioate, $C_5H_{12}NO_4PS$, M_r 213.2, *mp* – 28 °C (decomp.), *bp* ca. 135 °C, is a colorless liquid which is readily soluble in water, alcohols, acetone, and many hydrocarbons, slightly soluble in diethyl ether, and almost insoluble in petroleum ether [20, p. 896].

Omethoate is produced by reaction of *O,O*-dimethylphosphorylmercaptoacetic acid with methyl isocyanate [40].

Omethoate (announced in 1959) is used for control of spider mites, aphids, beetles, caterpillars, scale insects, thrips, and other pests on fruit, hops, cereal, rice, ornamentals, and other crops.
Trade Name. Folimat (Bayer).

Oxamyl [*23135-22-0*], *N,N*-dimethyl-2-methylcarbamoylimino-2-(methylthio)acetamide, $C_7H_{13}N_3O_3S$, M_r 219.3, *mp* 100 – 102 °C, consists of colorless crystals which are readily soluble in water, methanol, ethanol, acetone, and fairly soluble in toluene [20, p. 909].

Oxamyl is produced by chlorination of the oxime of methylglycolate, reaction with methanethiol and alkali, and conversion to the carbamate with methyl isocyanate [41].

Oxamyl (announced in 1968) is used for control of chewing and sucking insects, spider mites, and nematodes in ornamentals, vegetables, potatoes, and other crops.

Trade Name. Vydate (DU Pont).

Phenthoate [*2597-03-7*], *O,O*-dimethyl *S*-(α-carboethoxy)phenylmethyl phosphorodithioate, $C_{12}H_{17}O_4PS_2$, M_r 320.4, *mp* 186 – 187 °C, consists of colorless crystals which are slightly soluble in water but readily soluble in many organic solvents [20, p. 952].

Phenthoate is produced by reaction of the sodium salt of *O,O*-dimethyldithiophosphonic acid with phenylbromoethyl acetate [42].

Phenthoate (announced in 1955) is used for control of aphids, scale insects, jassids, lacebugs, etc., in cereals, maize, rice, coffee, sunflowers, sugar cane, and other crops.

Trade Names. Elsan (Nissan); Cidial (Isagro); Aimsan (Aimco).

Phorate [*298-02-2*], *O,O*-diethyl *S*-(2-ethylthio)methyl phosphorodithioate, $C_7H_{17}O_2PS_3$, M_r 260.4, *mp* < -15 °C, *bp* 118 – 120 °C (0.1 kPa), is a colorless liquid which is sparingly soluble in water but miscible with alcohols, ketones, ethers, and esters [20, p. 959].

Phorate is produced by reaction of *O,O*-diethyldithiophosphoric acid with ethanethiol and formaldehyde [43].

Phorate (announced in 1948) is a systemic insecticide and acaricide used for control of Agromyzidae, Aleyrodidae, Aphididae, Chrysomelidae, Noctuidae, Pyralidae, Tetranychidae, and certain nematodes in a variety of crops.

Trade Names. Thimet (Cyanamid); Ramcides (Kunurai); Umet (United Phosphorus).

Phosalone [*2310-17-0*], *O,O*-diethyl *S*-(6-chloro-2,3-dihydro-2-oxobenzoxazol-3-yl)methyl phosphorodithioate, $C_{12}H_{15}ClNO_4PS_2$, M_r 367.8, *mp* 42 – 48 °C, consists of colorless crystals which are sparingly soluble in water, fairly soluble in hexane, and readily soluble in many organic solvents [20, p. 961].

Phosalone is produced by treating *O,O*-diethyldithiophosphoric acid with *N*-chloromethyl-5-chlorobenzoxazolone [44].

Phosalone (announced in 1963) is used as a nonsystemic acaricide and insecticide, primarly in pome and stone fruit trees against Coleoptera, Homoptera, Lepidoptera and Thysanoptera.

Trade Name. Zolone (Rhône-Poulenc).

Phosmet [*732-11-6*], *O,O*-dimethyl *S*-(*N*-phthalimidomethyl) phosphorodithioate, $C_{11}H_{12}NO_4PS_2$, M_r 317.3, *mp* 72 – 72.7 °C, consists of colorless crystals which are sparingly soluble in water but readily soluble in acetone, toluene, xylene, and methanol [20, p. 963].

Phosmet is produced by reaction of *N*-chloromethylphthalimide with dimethyldithiophosphoric acid [45].

Phosmet (announced in 1961) is used for control of lepidopterous larvae, aphids, suckers,

fruit flies, and spider mites on pome fruit, stone fruit, citrus fruit, ornamentals, and vines.
Trade Names. Prolate (Gowan); Fosdan (General Quimica); Inovat (Productos OSA).

Phosphamidon [*13171-21-6*], *O,O*-dimethyl *O*-(2-chloro-2-diethylcarbamoyl-1-methyl)vinyl phosphate, $C_{10}H_{19}ClNO_5P$, M_r 299.7, *bp* 162 °C (2 kPa), is a pale yellow liquid which is miscible with water and many organic solvents with the exception of aliphatic hydrocarbons [20, p. 965].

(*E*)

(*Z*)

Phosphamidon is produced by reaction of trimethylphosphite with α,α-dichloroacetic acid diethylamide [46].

Phosphamidon (announced in 1956) is used for control of sucking, chewing, and boring insects, and spider mites on a wide range of crops.
Trade Names. Dimecron (Novartis); Rilan (Rallis); Kinadon (United Phosphorus).

Pirimiphos-methyl [*29232-93-7*], *O,O*-dimethyl *O*-2-diethylamino-6-methylpyrimidin-4-yl phosphorothioate, $C_{11}H_{20}N_3O_3PS$, M_r 305.3, *bp* 15 – 18 °C, is a straw-colored liquid which is sparingly soluble in water but miscible with most organic solvents [20, p. 988].

Pirimiphos-methyl is produced by condensation of diethylguanidine with ethyl acetate, followed by reaction with dimethylphosphoryl chloride [47].

Pirimiphos-methyl (announced in 1966) is used for control of a wide range of insects and mites in warehouses, stored grain, and animal houses, as well as industrial and domestic premises.
Trade Names. Actellic (Zeneca); Actellifog (Hortochem).

Profenofos [*41198-08-7*], *O*-4-bromo-2-chlorophenyl *O*-ethyl *S*-propyl phosphorothioate, $C_{11}H_{15}BrClO_3PS$, M_r 373.6, *bp* 100 °C (1.8 Pa), is a pale yellow liquid which is sparingly soluble in water but readily miscible with most organic solvents [20, p. 1006].

Profenofos is produced by reaction of *O*-(4-bromo-2-chlorophenyl) *O,O*-diethyl thiophosphate with propylbromide and triethylenediamine in acetonitrole [48].

Profenofos (announced in 1975) is used for control of insects, particularly Lepidoptera, and mites on cotton, maize, sugar beet, soya beans, potatoes, vegetables, tobacco, and other crops.
Trade Names.Curacron (Novartis); Sanofos (Sanonda).

Quinalphos [*13593-03-8*], *O,O*-diethyl *O*-quinoxalin-2-yl phosphorothioate, $C_{12}H_{15}N_2O_3PS$, M_r 298.3, *mp* 31 – 32 °C, consists of colorless crystals which are sparingly soluble in water but readily soluble in many organic solvents [20, p. 1077].

Quinalphos is produced by cyclization of *o*-phenylenediamine with chloroacetic acid, oxidation of the resulting 2-hydroxyquinoxaline and reaction with diethylthiophosphoryl chloride [49].

Quinalphos (announced in 1969) is used to control many insect pests such as Lepidoptera, Coleoptera and Diptera on fruit trees, cotton, vegetables, peanuts, and many other crops.
Trade Names. Ekalux (Novartis); Hubelux (Sanonda); Starlux (Shaw Wallace).

Sulfotepp [*3689-24-5*], *O,O,O′,O′*-tetraethyl dithiopyrophosphate, $C_8H_{20}O_5P_2S_2$, M_r 322.3, *bp* 136 – 139 °C (266 Pa), is a pale yellow liquid which is sparingly soluble in water but miscible with most organic solvents [20, p. 1131].

Sulfotepp is produced by reaction of diethylthionophosphoric acid chloride with water in the presence of pyridine and potassium carbonate [50].

Sulfotepp (announced in 1944) is used for fumigation control of aphids, thrips, spider mites, and whiteflies on glasshouse crops, and sciarid flies and phorid flies on mushrooms.
Trade Name. (Bayer).

Thiometon [*640-15-3*], *O,O*-dimethyl *S*-(2-ethylthio)ethyl phosphorodithioate, $C_6H_{15}O_2PS_2$, M_r 246.3, *bp* 110 °C (13 Pa), is a colorless liquid which is sparingly soluble in water but readily soluble in common organic solvents [20, p. 1199].

Thiometon is produced by reaction of the sodium salt of *O,O*-dimethyldithiophosphoric acid with ethylmercaptochloroethanol [51].

Thiometon (announced in 1952) is used for control of sucking insects, bryobia mites, tetranychid mites, and fruit-tree red spider mites on a wide range of crops.
Trade Name. Mavrik (Novartis).

Triazophos [*24017-47-8*], *O,O*-diethyl *O*-1-phenyl-1*H*-1,2,4-triazol-3-yl phosphorothioate, $C_{12}H_{16}N_3O_3PS$, M_r 313.3, *mp* −2 to −5 °C, is a pale yellow oil which is sparingly soluble in water and readily soluble in acetone, dichloromethane, methanol, isopropanol, ethyl acetate [20, p. 1226].

Triazophos is produced by reaction of 1-phenyl-3-hydroxy-1*H*-1,2,4-triazole, suspended in acetone, with diethoxythiophosphoryl chloride in the presence of triethylamine [52].

Triazophos (announced in 1970) is used for control of aphids, thrips, midges, beetles, lepidopterous larvae, and other soil insects, spider mites and other species of mites in ornamentals, fruit trees, vines, bananas, and many other crops.
Trade Names. Hostthion, Trilka, Spark (AgrEvo); Try (Sanonda).

Vamidothion [*2275-23-2*],*O,O*-dimethyl *S*-2-(1-methylcarbamoylethylthio)ethyl phosphorodithioate, $C_8H_{18}NO_4PS_2$, M_r 287.3, *mp* 43 °C, consists of colorless crystals which are readily soluble in water, benzene, toluene, acetonitrile, dichloromethane, cyclohexanone, and chloroform and sparingly soluble in cyclohexane, petroleum ether [20, p. 1263].

Vamidothion is produced by reaction of *O,O*-dimethylphosphoric acid chloride with the sodium salt of *N*-methylcarbamylethylmercaptoethanethiol [53].

Vamidothion (announced in 1962) is a systemic insecticide and acaricide that provides persistent control of *Eriosoma lanigerum* and other piercing and sucking Homoptera in cotton, hops, pome and stone fruit, and rice.
Trade Name. Kilval (Rhône-Poulenc).

3.2. Pyrethroids

Some pyrethroids, with their toxicity to insects, show acaricidal activity initially, but later the

mite population often increases [54]. It is improbable that pyrethroids will be able to provide long-term solutions to mite problems.

Acrinathrin [*101007-06-1*], (*S*)-α-cyano-3-phenoxybenzyl-(*Z*)-(1*R*,3*S*)-2,2-dimethyl-3-[2-(2,2,2-trifluoro-1-trifluoromethylethoxycarbonyl)vinyl]cyclopropanecarboxylate, $C_{26}H_{21}F_6NO_5$, M_r 541.4, *mp* 81.5 °C, consists of colorless crystals which are sparingly soluble in water, and moderately to highly soluble in most organic solvents [20, p. 16].

Acrimathrin is produced by esterification of 2,2-dimethyl-3-[3-oxo-3-{2,2,2-trifluoro-1-(trifluoromethyl)ethoxy}-1-propenyl]cyclopropanecarboxylic acid with cyano(3-phenoxyphenyl)methanol [55].

Acrimathrin (announced in 1983) acts on the central nervous system and is a contact and stomach acaricide/insecticide. It is effective against a wide range of phytophagous mites on vegetables, fruits, hops, ornamentals, vines, tobacco, and other crops.

Trade Name. Rufast (AgrEvo).

Bifenthrin [*82657-04-3*], 2-methylbiphenyl-3-methyl-(*Z*)-(1*RS*,3*RS*)-3-(2-chloro-3,3,3-trifluoroprop-1-enyl)-2,2-dimethylcyclopropanecarboxylate, $C_{23}H_{22}ClF_3O_2$, M_r 422.9, *mp* 51 – 56 °C, is a viscous liquid, crystalline or waxy product which is sparingly soluble in water, slightly soluble in heptane, methanol, soluble in acetone, chloroform, diethyl ether, and toluene [20, p. 118].

Bifenthrin is produced by reaction of 3-(2-chloro-3,3,3-trifluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylic acid with 3-(bromomethylene-2-methyl)biphenyl in the presence of potassium hydroxide [56].

Bifenthrin (announced in 1984) is effective against a broad range of foliar pests. It also controls some species of Acarina on cereals, citrus, cotton, fruits, grapes, and ornamentals.

(*Z*)-(1*R*)-*cis*-

(*Z*)-(1*S*)-*cis*-

Trade Name. Talstar (FMC).

Fenpropathrin [*64257-84-7*], (*R,S*)-α-cyano-3-phenoxybenzyl 2,2,3,3-tetramethylcyclopropanecarboxylate, $C_{22}H_{23}NO_3$, M_r 349.4, *mp* 45 – 50 °C, is a yellow-brown solid which is sparingly soluble in water and soluble in xylene, cyclohexanone, and methanol [20, p. 524].

Fenpropathrin is produced by reaction of α-cyano-3-phenoxybenzyl alcohol with 2,2,3,3-tertamethylcyclopropanecarboxylic acid chloride [57].

Fenpropathrin (announced in 1981) is used to control many species of mites and insects on fruits, vegetables, field crops, ornamentals, and cotton.

Trade Names. Danitol (Valent/Sumitomo); Rody (Sumitomo/Cyanamid).

Fenvalerate [*51630-58-1*], (*R,S*)-α-cyano-3-phenoxybenzyl-(*R,S*)-2-(4-chlorophenyl)-3-methylbutyrate, $C_{25}H_{22}ClNO_3$, M_r 419.9, *mp* 39.5 – 53.7 °C, is a viscous yellow or brown liquid product, sometimes partly crystalline at room temperature, which is practically insoluble in water, moderately soluble in hexane and methanol, and soluble in xylene [20, p. 539].

Fenvalerate is produced by reaction of α-cyano-3-phenoxybenzyl alcohol with 2-(4-chlorophenyl)-3-methylbutyric acid chloride [58].

Fenvalerate (announced in 1974) is used to control a wide range of pests, including those resistant to organochlorine, organophosphorous, and carbamate insecticides, in fruits, vines, olives, hops, nuts, vegetables, cotton, and oilseed rape.

Trade Names. Sumicidin (Sumitomo); Sanvalerate (Sanachem); Shasicidin (Sanonda).

Halfenprox [*111872-58-3*], 2-(4-bromodifluoromethoxyphenyl)-2-methylpropyl-3-phenoxybenzyl ether, $C_{24}H_{23}BrF_2O_3$, M_r 477.3, *bp* 291 °C, is a colorless clear liquid which is sparingly soluble in water [20, p. 654].

Halfenprox is produced by reaction of 3-phenoxybenzyl-2-(4-hydroxyphenyl)-2-methyl propyl ether and the potassium salt of *tert*-butanol with difluorodibromomethane in 1,3-dimethyl-2-imidazolidinone [59].

Halfenprox (announced in 1987) is a broad-spectrum acaricide with contact activity, it controls all stages of red spider mites, fruit tree red mites, two-spotted spider mites, and rust mites on citrus fruit, vines, tea, ornamentals, and other crops.

Trade Names. Anniverse, Sirbon (Mitsui Toatsu).

3.3. Formamidines

Products derived from the formamidines are used both as acaricides and as effective and selective insecticides. This class of compounds acts mainly as an ovicide on mites.

Amitraz [*33089-61-1*], N^1-methyl-N^2-(2,4-xylyl)-N^1-[*N*-(2,4-xylyl)-formimidoyl] formamidine, $C_{19}H_{23}N_3$, M_r 293.4, *mp* 86 – 87 °C, colorless needles, has low solubility in water (ca. 1 mg/L at 20 °C) but is soluble in acetone and toluene [16, p. 15].

Amitraz is produced by the reaction of 2,4-xylidine, ethylorthoformate, and methylamine [60].

Amitraz is active against a wide range of mites and against all stages of phytophagous mites [61].

Trade Names. Taktic, Mitac (AgrEvo, NOR-AM); ByeBye (Agriphar); Edrizer (Siapa); Sender (Sanonda).

Formetanate [*22259-30-9*], 3-(dimethylaminomethyleneamino)phenyl *N*-methylcarbamate, $C_{11}H_{15}N_3O_2$, M_r 221.3, *mp* 102 °C, yellow crystals, negligible vapor pressure, has a solubility in water of < 1 g/L at 20 °C and is soluble in acetone, chloroform, and methanol [17, p. 5], [16, p. 284].

Formetanate is produced by the reaction of 3-dimethylaminomethyleneaminophenol with methyl isocyanate [62].

Formetanate is active against the mobile stages of fruit tree spider mites and is recommended also for use in greenhouses.

Trade Names. Dicarzol (AgrEvo); Carzol (NOR-AM).

3.4. Nitrophenyl Esters

These compounds are effective as fungicides against powdery mildews and as acaricides. The compounds are nonsystemic and are less phytotoxic than the corresponding phenols.

Dinobuton [*973-21-7*], 2-*sec*-butyl-4,6-dinitrophenyl isopropyl carbonate, $C_{14}H_{18}N_2O_7$, M_r 326.3, *mp* 60 – 62 °C, yellow crystals, negligible vapor pressure at room temperature, is insoluble in water but soluble in most organic solvents [16, p. 207], [17, p. 3], [18, p. 540].

Dinobuton is produced by esterification of 2-*sec*-butyl-4,6-dinitrophenol with isopropyl chloroformate [63].

Dinobuton is used against red spider mites in greenhouses and in the field.

Trade Names. Acrex (Keno Gard AB, Murphy, Wacker); Dessin (Union Carbide).

Dinocap [*39300-45-3*], 2-(1-methylheptyl)-4,6-dinitrophenyl crotonate, $C_{18}H_{24}N_2O_6$, M_r 364.4, *bp* 138 – 140 °C at 6.7×10^{-5} kPa, dark brown liquid, very low vapor pressure at 20 °C, is insoluble in water but soluble in most organic solvents [19, p. 305].

Dinocap is produced by nitration of *o*-(1-methylheptyl)phenol followed by esterification with crotonic acid [64]. The industrial product is a mixture of isomers [65] and is analyzed by the Kjeldahl method [66].

Trade Name. Acrex (Efthymiadis).

3.5. Sulfonic Acid Esters

Compounds in this class show mainly contact activity and have long residual effects without any adverse phytotoxic effects.

Tetradifon [*116-29-0*], 4-chlorophenyl-2,4,5-trichlorophenyl sulfone $C_{12}H_6Cl_4O_2S$, M_r 356.0, *mp* 146.5 – 147.5 °C, colorless crystals, vapor pressure 3.2×10^{-11} kPa at 20 °C, is slightly soluble in water, has low solubility in acetone and alcohols, but is more soluble in aromatic hydrocarbons, chloroform, and dioxane [16, p. 505], [17, p. 4], [18, p. 543].

Tetradifon is produced by the Friedel – Crafts reaction of 2,4,5-trichlorobenzenesulfonyl chloride and chlorobenzene [67].

Tetradifon is recommended for use on tree fruit, citrus, grapes, vegetables, ornamental plants, and nursery stock.

Trade Names. Tedion V-18 (Uniroyal); Duracide (Endura); Tedone (Siapa).

3.6. Halogenated Benzhydrol Derivatives

These selective contact acaricides show activity toward a large variety of phytophagous mites. They are active against all postembryonal stages and eggs and are further characterized by their nonsystemic and good residual activity. Despite their resemblance to DDT they show no insecticidal activity.

Bromopropylate [*18181-80-1*], isopropyl-4,4′-dibromobenzilate $C_{17}H_{16}Br_2O_3$, M_r 428.1, *mp* 76 – 78 °C, colorless crystals, vapor pressure 6.8×10^{-9} kPa at 20 °C, is almost insoluble in water (< 10 mg/L at 20 °C) but soluble in most organic solvents [16, p. 54], [17, p. 5].

Bromopropylate is produced by esterification of 4,4′-dibromobenzilic acid with 2-propanol [68].

Bromopropylate is used against mites on citrus, grapes, cotton, vegetables, soybeans, apple and stone fruit, and ornamentals.

Trade Name. Neoron (Novartis).

Dicofol [*115-32-2*], 2,2,2-trichloro-1,1-bis(4-chlorophenyl)ethanol $C_{14}H_9Cl_5O$, M_r 370.5, *mp* 78.5 – 79.5 °C, colorless crystals, very low vapor pressure at 20 °C, is practically insoluble in water but soluble in most organic solvents [16, p. 183], [17, p. 4], [18, p. 534].

Dicofol is produced by chlorination of chlorfenethol [69] or by partial hydrolysis of 1,1,1,2-tetrachloro-2,2-bis(4-chlorophenyl)ethane with 80 – 90 % formic acid in the presence of a sulfonic acid at 120 – 125 °C [70].

Dicofol has been used successfully against spider mites on citrus, cotton, deciduous fruit, and other crops.

Trade Names. Kelthane (Rohm & Haas); Acarin, Mitigan (Makhteshim-Agan); Cecudifol (Ceguisa).

3.7. Organometallic Compounds

Chemicals of this class, all tin compounds, have opened a new era in mite control and are among the most important acaricides in use. They are characterized by their nonsystemic and excellent residual effectiveness. They control the mobile stages of a large variety of mites and show little phytotoxicity.

Azocyclotin [*41083-11-8*], 1-tricyclohexyltin-1*H*-1,2,4-triazole, $C_{20}H_{35}N_3Sn$, *M* 436.2, *mp* 218.8 °C, colorless crystals, vapor pressure $< 5\times10^{-6}$ kPa at 25 °C, is practically insoluble in water, and slightly soluble in cyclohexane, dichloromethane, toluene, and 2-propanol [19, p. 44].

Azocyclotin is produced by the reaction of tricyclohexyltin chloride with the sodium salt of 1,2,4-triazole or by the reaction of 1,2,4-triazole with bis-tricyclohexyltin oxide [71].

Azocyclotin shows activity against a broad spectrum of spider mites [71].

Trade Name. Peropal (Bayer)

Cyhexatin [*13121-70-5*], tricyclohexyltin hydroxide, $(C_6H_{12})_3SnOH$, $C_{18}H_{34}OSn$, M_r 385.2, *mp* 195 – 198 °C, colorless crystals, vapor pressure negligible at 25 °C, is practically insoluble in water (< 1 mg/L at 25 °C), soluble in acetone, chloroform, and methanol, but otherwise has low solubility in most organic solvents [17, p. 6], [18, p. 142].

Cyhexatin is produced by the Grignard reaction of cyclohexylmagnesium chloride with tin tetrachloride followed by hydrolysis with aqueous sodium hydroxide [72].

Cyhexatin is an effective acaricide against a wide range of mites, mainly in deciduous fruit. It acts is by contact against the mobile stages [57].

Trade Names. Acarotine (Siapra); Pennstyl (Elf Atochem); Aramol (Diachem).

Fenbutatin oxide [*13356-08-6*], bis[tris(2-methyl-2-phenylpropyl)tin] oxide, $C_{60}H_{78}OSn_2$, M_r 1053, *mp* 138 – 139 °C, colorless crystalline powder, is insoluble in water, but soluble in acetone, dichloromethane, and benzene [16, p. 259].

Fenbutatin oxide is produced by the treatment of tris(2-methyl-2-phenylpropyl)tin chloride with sodium hydroxide [74].

Fenbutatin oxide gives effective control of mites on citrus, fruit, vines, and ornamental plants.

Trade Names. Osaden, Torque (Cyanamid); Vendex (Cyanamid, DuPont).

3.8. Other Compounds

Abamectin [*7151-41-2*], a mixture containing at least 80 % avermectin B_{1a} ($C_{48}H_{72}O_{14}$, M_r 873.1) and not more than 20 % avermectin B_{1b} ($C_{47}H_{70}O_{14}$, M_r 860.1), *mp* 150 – 155 °C,

consists of colorless to pale yellow crystals which are sparingly soluble in water, fairly soluble in chloroform, ethanol, methanol, *n*-butanol, and cyclohexane, and soluble in toluene, acetone, and isopropanol [20, p. 3].

Abamectin is obtained from fermentation of *Streptomyces overmitilis* [75].

Abamectin (announced in 1981) acts by stimulating the release of γ-aminobutyric acid, an inhibitory neurotransmitter. It is an insecticide and acaricide with contact and stomach action that is used to control motile stages of mites, leaf miners, suckers, and other pests, on vegetables, fruits, and other crops.

Trade Names. Dynamec (Merck); Abacide (Mauget).

Benzoximate [*29104-30-1*], 3-chloro-α-ethoxyimino-2,6-dimethoxybenzyl benzoate, $C_{18}H_{18}ClNO_5$, M_r 363.8, *mp* 73 °C, colorless crystalline solid, is practically insoluble in water but soluble in benzene, hexane, xylene, and dimethylformamide [16, p. 35].

Benzoximate is produced by reaction of ethyl-3-chloro-2,6-dimethoxyhydroximate with benzoyl chloride in the presence of a base [76].

Benzoximate is a nonsystemic acaricide for use against mites on apples and citrus fruits.

Trade Names. Acarmate (Sipcam); Artaban (Procida); Citrazon (Nippon Soda).

Buprofezin [*69327-76-0*], 2-*tert*-butylimino-3-isopropyl-5-phenyl-1,3,5-thiazinan-4-one, $C_{16}H_{23}N_3OS$, M_r 305.4, *mp* 104.5 – 105.5 °C, consists of colorless crystals which are sparingly soluble in water but soluble in most organic solvents [20, p. 157].

Buprofezin is prepared by cyclocondensation of *N*-phenyl-*N′*-*tert*-butylthiourea with *N*-methylenechloride *N*-carbonylchloride-2-propylamine [77].

Buprofezin (announced in 1981) is probably a chitin synthesis and prostaglandin inhibitor. It inhibits moulting of nymphs and larvae and also suppresses oviposition by adults. It is effective against Cicadellidae and Homoptera in rice, Cicadellidae in potatoes, and Aleyrodidae in citrus, cotton, and vegetables.

Trade Name. Applaud (Nihon Nohyaku).

Chinomethionate [*2439-01-2*], quinomethionate, 6-methyl-[1,3]dithiolo[4,5-*b*]quinoxalin-2-one, $C_{10}H_6N_2OS_2$, M_r 234.3, *mp* 171 – 172 °C, yellow crystals, vapor pressure 2.7×10^{-8} kPa at 20 °C, is practically insoluble in water but soluble in dimethylformamide, cyclohexanone, and petroleum oils [16, p. 463], [17, p. 6], [18, p. 561].

Chinomethionate is produced by the reaction of carbonyl chloride with 6-methyl-2,3-quinoxalinedithiol in aqueous alkaline solution [79].

Chinomethionate is a nonsystemic acaricide useful against mites on fruits, vegetables, and ornamental plants [80].

Trade Name. Morestan (Bayer)

Clofentezine [*74115-24-5*], 3,6-bis-(2-chlorophenyl)-1,2,4,5-tetrazine, $C_{14}H_8Cl_2N_4$, M_r 303.1, *mp* 182.3 °C, forms magenta crystals which are sparingly soluble in water, moderately soluble in hexane, ethanol, and fairly soluble in dichloromethane, and acetone [20, p. 254].

Clofentezine is obtained by treatment of 2-chlorobenzoylchloride with hydrazine [81].

Clofentezine (announced in 1981) is a specific acaricide with contact action and prolonged residual activity. It inhibits embryo development. It is used to control eggs and young motile

R = CH_3: Abamectin B_{1a}

R = H : Abamectin B_{1b}

stages of *Panonychus ulmi* and *Tetranychus* spp. on pome fruit, stone fruit, nuts, vines, and hops.
Trade Name. Apollo (AgrEvo).

Cymizaol [*61676-87-7*], *N*-2,3-dihydro-3-methyl-1,3-thiazol-2-ylidene-2,4-xylidine, $C_{12}H_{14}N_2S$, M_r 218.3, *mp* 44 °C, forms colorless crystals which are sparingly soluble in water but soluble in benzene, methanol, dichloromethane, and hexane [20, p. 197].

Cymizaol is produced by cyclocondensation of *N*-2,4-dimethylphenyl-*N′*-methylthiourea with chloroacetaldehyde [78].

Cymizaol (announced in 1977) is used in dips or as a spray to control all Acarina species, including strains resistant to organochlorines, organophosphates, and carbamates.
Trade Name. Tifatol (Novartis).

Dienochlor [*2227-17-0*], perchlorobi(2,4-cyclopentadienyl), $C_{10}Cl_{10}$, M_r 474.6, *mp* 122 – 123 °C, tan crystalline solid, vapor pressure 10^{-6} kPa at 25 °C, is insoluble in water, slightly soluble in ethanol, acetone, and aliphatic hydrocarbons, and moderately soluble in aromatic hydrocarbons [16, p. 186], [18, p. 529].

Dienochlor is produced by the catalytic reduction of hexachlorocyclopentadiene [82], [83].

Dienochlor is used mainly for control of mites on ornamentals and may act as an inhibitor of oviposition.
Trade Name. Pentac (Novartis).

Endosulfan [*115-29-7*], 6,7,8,9,10,10-hexachloro-1,5,5a,6,9,9a-hexahydro-6,9-methano-2,4,3-benzodioxathiepine 3-oxide, $C_9H_6Cl_6O_3S$, M_r 406.9, *mp* > 80 °C, consists of colorless crystals which are sparingly soluble in water but readily soluble in ethyl acetate, dichloromethane, toluene, ethanol, and hexane [20, p. 459].

Endosulfan is produced by reaction of 1,2,3,4,7,7-hexachloro-5,6-dihydroxymethylbicylo[2,2,1]-hept-5-ene, obtained by condensation of *cis*-1,4-dihydroxybut-2-ene with hexachlorocyclopentadiene, with thionyl chloride [84].

Endosulfan (announced in 1956) acts as an antagonist of the GABA receptor chloride channel complex, and is used to control sucking, chewing, and boring insects and mites on a broad range of crops.
Trade Names. Fan (FMC); Thiodan (AgrEvo); Thionex (Makhteshim-Agan).

Fenazaquin [*120928-09-8*], 4-*tert*-butylphenylmethyl quinazolin-4-yl ether, $C_{20}H_{22}N_2O$, M_r 306.4, *mp* 77.5 – 80 °C, consists of colorless crystals which are practically insoluble in water but soluble in many organic solvents [20, p. 506].

Fenazaquin is produced by reaction of 4-hydroxyquinazoline with phosphite and chlorine, and treating the resulting haloquinazoline with 4-*tert*-butylphenylethanol [85].

Fenazaquin (announced in 1992) affects the metabolism by inhibiting the mitochondrial electron transport chain by binding with complex I at coenzyme Q. It is a contact acaricide with good knockdown activity on motile forms, as well as true ovicidal activity, preventing eclosion of mite eggs. It is used against *Eutetranychus*, *Panonychus* and *Tetranychus* spp., and *Brevipalpus phoenics* in almonds, apples, citrus, cotton, grapes, and ornamentals.
Trade Name. Magister (DowElanco).

Fenpyroximate [*111812-58-9*], *tert*-butyl (*E*)-α-(1,3-dimethyl-5-phenoxypyrazol-4-yl-methyleneaminooxy)-*p*-toluate, $C_{24}H_{27}N_3O_4$, M_r 421.5, *mp* 101.1 – 102.4 °C, is a colorless crystalline powder which is practically insoluble in water, moderately soluble in methanol, and highly soluble in acetone, dichloromethane, chloroform, and THF [20, p. 530].

Fenpyroximate is produced by reaction of *tert*-butyl 4-(bromomethyl)benzoate with 1,3-dimethyl-5-phenoxypyrazole-4-carboxaldehyde oxime in the presence of potassium hydroxide in dimethylsulfoxide [86].

Fenpyroximate (announced in 1990) inhibits mitochondrial electron transport at complex I; it possesses quick knockdown activity against larvae, nymphs and adults. It is used to control important phytophagous mites such as Tetranychidae, Tarsonemidae, and other pests on citrus, apples, pears, grapes, tea, cherries, and melons.
Trade Names. Danitorante, Danitron (Nihon Noyaku).

Flucycloxuron [*94050-52-9*], 1-[α-(4-chloro-α-cyclopropylbenzylideneamino-oxo)-*p*-tolyl]-3-(2,6-difluorobenzoyl)urea, $C_{25}H_{20}ClF_2N_3O_3$, M_r483.9, *mp* 143.6 °C, consists of off-white to yellow crystals which are insoluble in water, sparingly soluble in cyclohexane, xylene, ethanol, and soluble in *N*-methylpyrrolidone [20, p. 562].

Flucycloxuron is produced by reaction of 4-chlorocyclopropylphenone with hydroxylamine to yield the corresponding oxime, which is treated with 4-nitrobenzylbromide, followed by reduction to give the corresponding amine, which is further treated with 2,6-difluorobenzoyl isocyanate [87].

Flucycloxuron (announced in 1988) is a chitin synthesis inhibitor that is only active against egg and larval stages (does not affect adult mites and insects). It is used on a variety of crops.
Trade Name. Andalin (Uniroyal).

Flufenoxuron [*101463-69-8*], 1-[-4-(2-chloro-α,α,α-trifluoro-*p*-tolyloxy)-2-fluorophenyl]-3-(2,6-difluorobenzoyl)urea, $C_{21}H_{11}ClF_6N_2O_3$, M_r 488.8, *mp* 169 – 172 °C, is a colorless crystalline solid which is practically insoluble in water and moderately soluble in acetone, xylene, dichloromethane [20, p. 568].

Flufenoxuron is produced by reaction of 2-fluoro-4-hydroxyaniline in potassium hydroxide-containing dimethyl sulfoxide with 3,4-dichlorotrifluoromethyltoluene to give the corresponding phenoxyaniline, which is treated with 2,6-difluorophenyl isocyanate [88].

Flufenoxuron is a chitin synthesis inhibitor and insect and acarid growth regulator with contact and stomach action. It is used for control of immature stages of many phytophagous mites and insect pests on pome fruits, vines, citrus fruits, tea, cotton, maize, vegetables, ornamentals, etc.

Trade Name. Cascade (Cyanamid).

Hexythiazox [*78587-05-0*], (4*RS*,5*RS*)-5-(4-chlorophenyl)-*N*-cyclohexyl-4-methyl-2-oxo-1,3-thiazolidine-3-carboxamide, $C_{17}H_{21}ClN_2O_2S$, M_r 352.9, *mp* 108.0 – 108.5 °C, consists of colorless crystals which are sparingly soluble in water, fairly soluble in hexane, acetonitrile, and soluble in chloroform, methanol, and acetone [20, p. 679].

Hexythiazox is produced by treatment of *trans*-4-methyl-5-(4-chlorophenyl)-2-thiazolidinone with phenylisocyanate [89].

Hexythiazox (announced in 1982) possesses ovicidal, larvicidal, and nymiphicidal activity. It is used against eggs and larvae of many phytophagous mites on fruit, vines, vegetables, and cotton.

Trade Names. Cesar (AgrEvo); Zeldox (Zeneca); Ordoval (BASF); Matacar (Sipcam); Hexygon (Gowen).

Lufenuron [*103055-07-8*], (*RS*)-1-[2,5-dichloro-4-(1,1,2,3,3,3-hexafluoropropoxy)phenyl] 3-(2,6-difluorobenzoyl)urea, $C_{17}H_8Cl_2F_8N_2O_3$, M_r 511.2, *mp* 164.7 – 167.7 °C, forms colorless crystals which are practically insoluble in water, moderately soluble in ethanol, toluene, *n*-octanol, and *n*-hexane, and readily soluble in acetone [20, p. 753].

Lufenuron is produced by condensation of 2,5-dichloro-4-(1,1,2,3,3,3-hexafluoropropyloxy)aniline with 2,4-difluorobenzyl isocyanate in anhydrous toluene [90].

Lufenuron inhibits chitin synthesis and acts mostly by ingestion; larvae are unable to molt and also cease feeding. It is used for control of Lepidoptera and Coleoptera larvae on cotton, maize, and vegetables and citrus whiteflies and rust on citrus fruit.

Trade Name. Match (Novartis).

Propargite [*2312-35-8*], 2-(4-*tert*-butylphenoxy)cyclohexyl 12-propynyl sulfite, $C_{29}H_{26}O_4S$, M_r 350.5; the technical product is a dark, viscous oil, d_4^{25} 1.085 – 1.115, practically insoluble in water but soluble in most organic solvents [16, p. 447], [17, p. 4], [18, p. 560].

Proargite is produced by the reaction of 4-*tert*-butylphenol with 1,2-epoxycyclohexane, followed by treatment with thionyl chloride to give the chlorosulfinate, then with 2-propynol (propargyl alcohol) in the presence of a base [91].

Propargite is used mainly for the control of mites on fruit and other crops.

Trade Names. Omite (Uniroyal); Redador (Productos OSA).

Pyridaben [*96489-71-3*], 2-*tert*-butyl-5-(4-*tert*-butylbenzylthio)-4-chloropyridazin-3-(2*H*)-one, $C_{19}H_{25}ClN_2OS$, M_r 364.9, *mp* 111 – 112 °C, consists of colorless crystals which are practically insoluble in water, moderately soluble in ethanol, hexane, and *n*-octanol, and readily soluble in acetone, benzene, xylene, and cyclohexane [20, p. 1061].

Pyridaben is produced by reaction of mucochloric acid with 4-*tert*-butylmercaptotoluene, followed by cyclocondensation of the resulting malealdehydic acid derivative with *N*-*tert*-butylhydrazine [92].

Pyridaben (announced in 1988) is active against all developing stages, especially against the larval and nymph stages, and is used for control of Acari, Aleyrodidae, Aphididae, Cicadellidae and Thysanoptera on field crops.

Trade Name. Sanmite (Nissan).

Tebufenpyrad [*119168-77-3*], *N*-(4-*tert*-butylbenzyl)-4-chloro-3-ethyl-1-methylpyrazole-5-carboxamide, $C_{18}H_{24}ClN_3O$, M_r 333.8, *mp* 61 – 61 °C, consists of colorless crystals which are sparingly soluble in water but soluble in acetone, methanol, chloroform, acetonitrile, hexane, and benzene [20, p. 1148].

Tebufenpyrad is produced by treatment of 4-chloro-1-methyl-3-ethyl-pyrazole-5-carboxylic acid with thionyl chloride under reflux, followed by reaction of the resulting acid chloride with 4-*tert*-butylbenzylamine [93].

Tebufenpyrad (announced in 1988) is a mitochondrial respiration inhibitor that acts in the electron transport chain at site I. It is a nonsystemic acaricide that acts by contact and ingestion. It is used for control of all stages of *Tetranychus*, *Panonychus*, *Origonychus*, and *Eotetranychus* spp. on top fruit, vines, citrus, vegetables, hops, ornamentals, melons, and cotton.

Trade Names. Comanché, Masai, Oscar (Cyanamid); Pyranica (Mitsubishi).

4. Toxicology

The following summary gives an overview of the toxicological profile of various acaricides. The data were assembled by searching the literature and databanks available to the public. Because most of these compounds are proprietary products, many of the toxicological data are not published. Information in well-documented monographs, (e.g., WHO/FAO), in which the original data from the companies are available, were preferred to other published data, (e.g., handbooks), because the studies submitted to WHO/FAO were performed according to internationally accepted test protocols and good laboratory practices. The values presented should be viewed as a broad estimate of human toxicity as limited by strain, number of animal tested, study design, and applicability of the biological model.

4.1. Organophosphates and (Oxime)Carbamates

Toxic Action. Cumulative inhibition of cholinesterase causes toxic effects at doses not effective acutely. Delayed neurotoxicity leading to demyelination is observed with compounds that inhibit neurotoxic esterase. Carbamates act similarly, but reactivation of esterase occurs more rapidly [94, p. 531, p. 539].

Aldicarb [*116-06-3*]

LD_{50} (rat, oral)	0.62 – 1.23	mg/kg	[95]
LD_{50} (mouse, oral)	0.58 – 1.5	mg/kg	[95]
LD_{50} (guinea pig, oral)	1.0	mg/kg	[95]
LD_{50} (rabbit, oral)	1.3	mg/kg	[95]
LD_{50} (chicken)	9.0	mg/kg	[95]
LD_{50} (rat, dermal)	3.2 to > 10	mg/kg	[95]
LD_{50} (rabbit, dermal)	5.0 to > 10	mg/kg	[95]
Rabbit: nonirritating to eyes and skin			[95]
Guinea pig: not a skin sensitizer			[95]
Nonmutagenic			[95]
NOEL/NOAEL:			
Reproduction.			
Rat (feed):	0.3	$mg\,kg^{-1}\,d^{-1}$	[96, p. 33]
Teratogenicity.			
Rat (gavage):	0.125	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[96, p. 33]
	0.25	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[96, p. 33]
Chronic.			
Rat (93-day feed):	0.1	$mg\,kg^{-1}\,d^{-1}$	[96, p. 33]
Mouse (103-week feed):	0.9	$mg\,kg^{-1}\,d^{-1}$	[96, p. 33]
Dog (one-year feed):	0.05	$mg\,kg^{-1}\,d^{-1}$	[96, p. 33]
Human.			
(single oral dose):	0.025	$mg\,kg^{-1}\,d^{-1}$ (cholinesterase)	[96, p. 33]

ADI: $0.003\,mg\,kg^{-1}\,d^{-1}$ [96, p. 33]

Chlorfenvinphos [*470-90-6*]

LD_{50} (rat, oral)	9.6 – 39	mg/kg	[97, p. 15]
LD_{50} (mouse, oral)	117 – 200	mg/kg	[97, p. 15]
LD_{50} (rabbit, oral)	300 – 1000	mg/kg	[97, p. 15]
LD_{50} (dog, oral)	> 12000	mg/kg	[97, p. 15]
LD_{50} (guinea pig, oral)	125 – 250	mg/kg	[97, p. 15]
LD_{50} (rat, dermal)	30 – 108	mg/kg	[97, p. 15]
LD_{50} (rabbit, dermal)	412 – 4700	mg/kg	[97, p. 15]
Rabbit: slightly irritating to skin			[97, p. 15]
Rabbit: nonirritating to eyes			[97, p. 15]
Nonmutagenic			[97, p. 15]
NOEL/NOAEL:			
Reproduction.			
Rat (two-generation feed):	0.05	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[97, p. 15]
Teratogenicity.			
Rat (gavage):	1.0	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[97, p. 15]
	7.0	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[97, p. 15]
Rabbit (gavage):	< 25	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[97, p. 15]
	100	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[97, p. 15]
Chronic.			
Rat (2-year feed):	0.15	$mg\,kg^{-1}\,d^{-1}$	[97, p. 15]
Mouse (2-year feed):	3.7	$mg\,kg^{-1}\,d^{-1}$	[97, p. 15]
Dog (one-year feed):	2.8	$mg\,kg^{-1}\,d^{-1}$	[97, p. 15]

ADI: $0.0005\,mg\,kg^{-1}\,d^{-1}$ [97, p. 15]

Chlorpyrifos-methyl [*5598-13-0*]

LD_{50} (rat, oral)	2680 – 3069	mg/kg	[98, p. 115]
LD_{50} (mouse, oral)	1122 – 2440	mg/kg	[98, p. 115]

NOEL/NOAEL:			
Reproduction.			
Rat (2-generation gavage):	0.5	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[117, p. 75]
Subchronic.			
Rat (3-month feed):	0.054	$mg\,kg^{-1}\,d^{-1}$	[117, p. 75]
Mouse (3-month feed):	0.137	$mg\,kg^{-1}\,d^{-1}$	[117, p. 75]

Chronic.			
Dog (one-year gavage):	0.5	$mg\,kg^{-1}\,d^{-1}$	[117, p. 75]
Human.			
(5-day oral):	0.08	$mg\,kg^{-1}\,d^{-1}$	[117, p. 75]

ADI: $0.008\,mg\,kg^{-1}\,d^{-1}$ [117, p. 75]

4.2. Pyrethroids

Toxic action. General nerve activation with convulsion, paralysis, and respiratory failure; *cis* isomers are metabolized poorly and have higher toxicity [94, p. 586].

Acrinathrin [*101007-06-1*]

LD_{50} (rat, oral)	>5000	mg/kg	[20, p. 16]
LD_{50} (mouse, oral)	>5000	mg/kg	[20, p. 16]
LD_{50} (rat, dermal)	>2000	mg/kg	[20, p. 16]
LC_{50} (rat, 4-h inhalation)	1.6	mg/L air	[20, p. 16]
Rabbit: nonirritating to skin and eyes			[20, p. 16]
Guinea pig: not a skin sensitizer			[20, p. 16]
Nonmutagenic			[20, p. 16]
NOEL/NOAEL:			
Subchronic.			
Rat (90-day feed):	2.4 – 3.1	$mg\,kg^{-1}\,d^{-1}$	[20, p. 16]
Chronic.			
Dog (one-year feed):	3.0	$mg\,kg^{-1}\,d^{-1}$	[20, p. 16]

ADI: $0.02\,mg\,kg^{-1}\,d^{-1}$ [20, p. 16]

Bifenthrin [*82657-04-3*]

LD_{50} (rat, oral)	56	mg/kg	[96, p. 79]
LD_{50} (mouse, oral)	43	mg/kg	[96, p. 79]
LD_{50} (rabbit, dermal)	>2000	mg/kg	[96, p. 79]
Rabbit: nonirritating to skin			[96, p. 79]
Rabbit: slightly irritating to eyes			[96, p. 79]
Guinea pig: not a skin sensitizer			[96, p. 79]
Nonmutagenic			[96, p. 79]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	3	$mg\,kg^{-1}\,d^{-1}$ (parental)	[96, p. 79]
	5	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[96, p. 79]
Teratogenicity.			
Rat (gavage):	1	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[96, p. 79]
	>2	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[96, p. 79]
Rabbit (gavage):	2.7	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[96, p. 79]
	>8	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[96, p. 79]
Chronic.			
Rat (2-year feed):	4	$mg\,kg^{-1}\,d^{-1}$ (males)	[96, p. 79]
	7.5	$mg\,kg^{-1}\,d^{-1}$ (females)	[96, p. 79]
Mouse (20-month feed):	7.6	$mg\,kg^{-1}\,d^{-1}$ (males)	[96, p. 79]
	37	$mg\,kg^{-1}\,d^{-1}$ (females)	[96, p. 79]
Dog (one-year capsule):	1.5	$mg\,kg^{-1}\,d^{-1}$ (females)	[96, p. 79]

ADI: $0.02\,mg\,kg^{-1}\,d^{-1}$ [96, p. 79]

Fenpropathrin [*64257-84-7*]

LD_{50} (rat, oral)	49 – 164	mg/kg	[99, p. 233]
LD_{50} (mouse, oral)	58 – 154	mg/kg	[99, p. 233]
LD_{50} (rabbit, oral)	510 – 675	mg/kg	[99, p. 233]
LD_{50} (dog, oral)	>1000	mg/kg	[99, p. 233]
LD_{50} (rat, dermal)	870 – 1600	mg/kg	[99, p. 233]
LD_{50} (mouse, dermal)	740 – 920	mg/kg	[99, p. 233]
LD_{50} (rabbit, dermal)	510 – 675	mg/kg	[99, p. 233]
LC_{50} (rat, 2-h inhalation)	>96	mg/L air	[99, p. 233]
LC_{50} (mouse, ?-h inhalation)	43 – 100	mg/L air	[99, p. 233]
Rabbit: slightly irritating to eyes			[99, p. 233]
Rabbit: nonrritating to skin			[99, p. 233]
Guinea pig: not a skin sensitizer			[99, p. 233]
Nonmutagenic			[99, p. 233]
NOEL/NOAEL:			
Reproduction.			
Rat (3-generation feed):	3	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[99, p. 233]
Teratogenicity.			
Rat (gavage):	3	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[99, p. 233]
	10	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[99, p. 233]
Rabbit (gavage):	4	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[99, p. 233]
	36	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[99, p. 233]
Chronic.			
Rat (2-year feed):	7	$mg\,kg^{-1}\,d^{-1}$	[99, p. 233]
Mouse (2-year feed):	56	$mg\,kg^{-1}\,d^{-1}$	[99, p. 233]
Dog (one-year feed):	3	$mg\,kg^{-1}\,d^{-1}$	[99, p. 233]

ADI: $0.03\,mg\,kg^{-1}\,d^{-1}$ [99, p. 233]

Fenvalerate [*51630-58-1*]

LD_{50} (rat, oral)	451	mg/kg (DMSO)	[118]
	> 3200	mg/kg (PEG/Water)	[118]
LD_{50} (mouse, oral)	100 – 300	mg/kg (DMSO)	[118]
	1002	mg/kg (PEG/Water)	[118]
LD_{50} (chinese hamster, oral)	83 – 98	mg/kg (DMSO)	[118]
LD_{50} (hen, oral)	> 1500	mg/kg	[118]
LD_{50} (rat, dermal)	5000	mg/kg	[118]
LD_{50} (rabbit, dermal)	1000 – 3200	mg/kg	[118]
LC_{50} (rat, 3-h inhalation)	> 101	mg/L air	[118]
LC_{50} (mouse, 3-h inhalation)	101	mg/L air	[118]
Rabbit: nonirritating to skin and eyes			[118]
Guinea pig: not a skin sensitizer			[118]
Nonmutagenic			[119, p. 299]
NOEL/NOAEL:			
Reproduction.			
Rat (3-generation feed):	2.5	$mg\,kg^{-1}\,d^{-1}$ (parental)	[118]
	2.5	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[118]
Teratogenicity.			
Mouse (gavage):	15	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[118]
	50	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[118]
Rabbit (gavage):	25	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[118]
	50	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[118]
Chronic.			
Rat (2-year feed):	12.5	$mg\,kg^{-1}\,d^{-1}$	[120]
Mouse (78-week feed):	11.9	$mg\,kg^{-1}\,d^{-1}$	[121]
Dog (90-day feed):	12.5	$mg\,kg^{-1}\,d^{-1}$	[119, p. 299]

ADI: $0.02\,mg\,kg^{-1}\,d^{-1}$ [122, p. 28]

Halfenprox [*111872-58-3*]

LD_{50} (rat, oral)	132 – 159	mg/kg	[20, p. 654]
LD_{50} (mouse, oral)	121 – 149	mg/kg	[20, p. 654]
LD_{50} (rat, dermal)	2000	mg/kg	[20, p. 654]
LC_{50} (rat, 4-h inhalation)	0.36 – 1.38	mg/L air	[20, p. 654]
NOEL/NOAEL:			
Chronic.			
Rat (2-year feed):	1.4	$mg\,kg^{-1}\,d^{-1}$	[20, p. 654]

ADI: $0.014\,mg\,kg^{-1}\,d^{-1}$ [20, p. 654]

4.3. Formamidines

Amitraz [*33089-61-1*]

LD_{50} (rat, oral)	600	mg/kg	[106, p. 1]
LD_{50} (mouse, oral)	> 1600	mg/kg	[106, p. 1]
LD_{50} (guinea pig, oral)	400 – 800	mg/kg	[106, p. 1]
LD_{50} (rabbit, oral)	> 100	mg/kg	[106, p. 1]
LD_{50} (dog, oral)	100	mg/kg	[106, p. 1]
LD_{50} (babboon, oral)	100 – 250	mg/kg	[106, p. 1]
LD_{50} (rat, dermal)	> 600	mg/kg	[106, p. 1]
LD_{50} (rabbit, dermal)	> 200	mg/kg	[106, p. 1]
LC_{50} (rat, 6-h inhalation)	65	mg/L air	[106, p. 1]
Rabbit: nonirritating to skin and eyes			[106, p. 1]
Guinea pig: not a skin sensitizer			[106, p. 1]
Nonmutagenic			[106, p. 1]
NOEL/NOAEL:			
Reproduction.			
Rat (3-generation feed):	1	$mg\,kg^{-1}\,d^{-1}$	[106, p. 1]
Teratogenicity.			
Rat (gavage):	1	$mg\,kg^{-1}\,d^{-1}$	[106, p. 1]
Chronic.			
Rat (two-year feed):	3	$mg\,kg^{-1}\,d^{-1}$	[123, p. 14]
Mouse (80-week feed):	2.5	$mg\,kg^{-1}\,d^{-1}$	[123, p. 14]
Dog (2-year feed):	0.25	$mg\,kg^{-1}\,d^{-1}$	[123, p. 14]

ADI: $0.003\,mg\,kg^{-1}\,d^{-1}$ [106, p. 1]

Formetanate [*22259-30-9*]

LD_{50} (rat, oral)	15 – 26	mg/kg	[100, p. 1159]
LD_{50} (mouse, oral)	13 – 25	mg/kg	[100, p. 1159]
LD_{50} (dog, oral)	19	mg/kg	[100, p. 1159]
LD_{50} (rabbit, dermal)	> 10200	mg/kg	[100, p. 1159]
LD_{50} (rat, dermal)	> 5600	mg/kg	[100, p. 1159]
LC_{50} (rat, 4-h inhalation)	0.28 – 2.9	mg/L air	[100, p. 1159]
Rabbit: irritating to eyes			[20, p. 623]
Guinea pig: skin sensitizer			[20, p. 623]
Nonmutagenic			[100, p. 1159]

NOEL/NOAEL:			
Teratogenicity.			
Not teratogenic			[100, p. 1159]
Reproduction.			
Rat (2-generation feed):	2.5	$g\,kg^{-1}\,d^{-1}$ (parental and developmental)	[106, p. 1]
Chronic.			
Rat (2-year feed):	0.52	$mg\,kg^{-1}\,d^{-1}$	[20, p. 623]
Mouse (2-year feed):	8.2	$mg\,kg^{-1}\,d^{-1}$	[20, p. 623]
Dog (one-year feed):	0.37	$mg\,kg^{-1}\,d^{-1}$	[20, p. 623]
ADI: 0.037 $mg\,kg^{-1}\,d^{-1}$ [20, p. 623]			

4.4. Nitrophenyl Esters

Toxic Action. Uncoupling of oxidative phosphorylation; cataract formation [94, p. 556].

Dinobuton [*973-21-7*]

LD_{50} (rat, oral)	140	mg/kg	[124]
LD_{50} (mouse, oral)	2540	mg/kg	[125]
LD_{50} (rat, dermal)	> 5000	mg/kg	[126]
NOEL/NOAEL:			
Chronic.			
Rat (2-year feed):	3 – 6	$mg\,kg^{-1}\,d^{-1}$	[127]
Dog (one-year feed):	4.5	$mg\,kg^{-1}\,d^{-1}$	[127]

Dinocap [*39300-45-31*]

LD_{50} (male rat, oral)	1581 – 2321	mg/kg	[128, p. 75]
LD_{50} (female rat, oral)	510 – 1493	mg/kg	[128, p. 75]
LD_{50} (mouse, oral)	150 – 180	mg/kg	[128, p. 75]
LD_{50} (rabbit, oral)	2000 – 3000	mg/kg	[128, p. 75]
LD_{50} (dog, oral)	100	mg/kg	[128, p. 75]
LD_{50} (rabbit, dermal)	> 4700		[128, p. 75]
LC_{50} (rat, 4-h inhalation)	0.36	mg/L air	[20, p. 426]
Rabbit: moderately to markedly irritating, to skin and eyes			[20, p. 426]
Nonmutagenic			[20, p. 426]
NOEL/NOAEL:			
Reproduction.			
Rat (feed):	6.4	$mg\,kg^{-1}\,d^{-1}$	[128, p. 75]
Teratogenicity.			
Mouse (gavage):	10	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[128, p. 75]
	40	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[128, p. 75]
Rat (gavage):	100	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[128, p. 75]
Syrian hamster (gavage):	25	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[128, p. 75]
	12.5	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[128, p. 75]
Rabbit (gavage):	0.5	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[128, p. 75]
Chronic.			
Rat (30-month feed):	6.4	$mg\,kg^{-1}\,d^{-1}$ (males)	[128, p. 75]
	8.1	$mg\,kg^{-1}\,d^{-1}$ (females)	[128, p. 75]
Dog (one-year feed):	0.4	$mg\,kg^{-1}\,d^{-1}$	[128, p. 75]
Eye cateracts in duck and rabbit: NOAEL (rabbit, gavage)	9	$mg\,kg^{-1}\,d^{-1}$	[128, p. 75]
ADI: 0.001 $mg\,kg^{-1}\,d^{-1}$ [128, p. 75]			

4.5. Sulfonic Acid Ester

Tetradifon [*116-29-0*]

LD_{50} (rat, oral)	> 14700	mg/kg	[20, p. 1177]
LD_{50} (rabbit, dermal)	> 10000	mg/kg	[20, p. 1177]
LC_{50} (rat, 4-h inhalation)	> 3	mg/L air	[20, p. 1177]
Rabbit: nonirritating to skin			[20, p. 1177]
Rabbit: slightly irritating to eyes			[20, p. 1177]
Nonmutagenic			[20, p. 1177]
Not teratogenic in rat and rabbit			[20, p. 1177]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	ca. 10	$mg\,kg^{-1}\,d^{-1}$	[20, p. 1177]
Chronic.			
Rat (2-year feed):	15	$mg\,kg^{-1}\,d^{-1}$ (males)	[20, p. 1177]

4.6. Halogenated Benzhydrol Derivatives

Bromopropylate [*18181-80-1*]

LD_{50} (rat, oral)	> 5000	mg/kg	[99, p. 39]
LD_{50} (mouse, oral)	8000	mg/kg	[99, p. 39]
LD_{50} (rabbit, oral)	> 6000	mg/kg	[99, p. 39]
LD_{50} (rat, dermal)	> 4000	mg/kg	[99, p. 39]
LD_{50} (rabbit, dermal)	> 2020	mg/kg	[99, p. 39]
LC_{50} (rat, 4-h inhalation)	> 4458	mg/L air	[99, p. 39]
Rabbit: nonirritating to eyes and skin			[99, p. 39]
Guinea pig: not a skin sensitizer			[99, p. 39]
Nonmutagenic			[99, p. 39]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	9	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[99, p. 39]
Teratogenicity.			
Rat (gavage):	50	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[99, p. 39]
	700	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[99, p. 39]
Rabbit (gavage):	20	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[99, p. 39]
	120	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[99, p. 39]
Chronic.			
Rat (2-year feed):	3.7	$mg\,kg^{-1}\,d^{-1}$	[99, p. 39]
Mouse (2-year feed):	16	$mg\,kg^{-1}\,d^{-1}$	[99, p. 39]
Dog (one-year feed):	2.7	$mg\,kg^{-1}\,d^{-1}$	[99, p. 39]

ADI: $0.03\,mg\,kg^{-1}\,d^{-1}$ [99, p. 39]

Dicofol [*115-32-3*]

LD_{50} (rat, oral)	587 – 595	mg/kg	[107, p. 137]
LD_{50} (mouse, oral)	669 – 675	mg/kg	[107, p. 137]
LD_{50} (rabbit, oral)	1820	mg/kg	[107, p. 137]
LD_{50} (dog, oral)	> 4000	mg/kg	[107, p. 137]
LD_{50} (rat, dermal)	> 5000	mg/kg	[107, p. 137]
LD_{50} (rabbit, dermal)	> 2500	mg/kg	[107, p. 137]
LC_{50} (rat, 4-h inhalation)	> 5	mg/L air	[107, p. 137]
Rabbit: nonirritating to eyes			[107, p. 137]
Rabbit: irritating to skin			[107, p. 137]
Guinea pig: not a skin sensitizer			[134]
Nonmutagenic			[107, p. 137]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	0.25	$mg\,kg^{-1}\,d^{-1}$ (parental)	[107, p. 137]
	2.1	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[107, p. 137]
Teratogenicity.			
Rat (gavage):	0.25	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[107, p. 137]
	25	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[107, p. 137]
Rabbit (gavage):	0.4	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[107, p. 137]
	4	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[107, p. 137]
Chronic.			
Rat (2-year feed):	0.22	$mg\,kg^{-1}\,d^{-1}$	[107, p. 137]
Mouse (78-week feed):	> 40	$mg\,kg^{-1}\,d^{-1}$	[107, p. 137]
Dog (one-year feed):	0.82	$mg\,kg^{-1}\,d^{-1}$	[107, p. 137]

ADI: $0.002\,mg\,kg^{-1}\,d^{-1}$ [107, p. 137]

4.7. Organometallic Compounds

Toxic Action. Interference with lymphocyte function; induction of heme oxygenase; decreased liver hemoprotein level [94, p. 353].

Azocyclotin [*41083-11-8*]

LD_{50} (rat, oral)	> 150	mg/kg	[116, p. 50]
LD_{50} (rat, oral)	209 – 363	mg/kg	[20, p. 69]
LD_{50} (guinea pig, oral)	261	mg/kg	[20, p. 69]
LD_{50} (mouse, oral)	870 – 980	mg/kg	[20, p. 69]
LD_{50} (rat, dermal)	> 5000	mg/kg	[116, p. 50]
LC_{50} (rat, 4-h inhalation)	~ 0.02	mg/L air	[116, p. 50]
Rabbit: irritating to skin and eyes			[116, p. 50]
Guinea pig: not a skin sensitizer			[116, p. 50]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	1.0	$mg\,kg^{-1}\,d^{-1}$	[129, p. 22]
Teratogenicity.			
Rabbit (gavage):	0.1	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[129, p. 22]
	1.0	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[129, p. 22]
Chronic.			
Rat (2-year feed):	0.25	$mg\,kg^{-1}\,d^{-1}$	[129, p. 22]
Mouse (2-year feed):	2.14	$mg\,kg^{-1}\,d^{-1}$	[129, p. 22]
Dog (2-year feed):	0.25	$mg\,kg^{-1}\,d^{-1}$	[129, p. 22]

ADI: $0.007\,mg\,kg^{-1}\,d^{-1}$ [129, p. 22]

Cyhexatin [*13121-70-5*]

LD_{50} (rat, oral)	540	mg/kg	[20, p. 302]
LD_{50} (rabbit, oral)	500 – 1000	mg/kg	[20, p. 302]
LD_{50} (guinea pig, oral)	780	mg/kg	[20, p. 302]
LD_{50} (rabbit, dermal)	> 2000	mg/kg	[20, p. 302]
Rabbit: irritating to eyes			[20, p. 302]
Rabbit: nonirritating to skin			[20, p. 302]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	0.1	$mg\,kg^{-1}\,d^{-1}$ (parental)	[113, p. 65]
	0.7	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[113, p. 65]
Teratogenicity.			
Rabbit (gavage):	0.75	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[113, p. 65]
Chronic.			
Mouse (2-year feed):	3	$mg\,kg^{-1}\,d^{-1}$	[113, p. 65]
Dog (one-year feed):	0.75	$mg\,kg^{-1}\,d^{-1}$	[98, p. 129]

ADI: $0.007\,mg\,kg^{-1}\,d^{-1}$ [113, p. 65]

Fenbutatin oxide [*13356-08-6*]

LD_{50} (rat, oral)	4400	mg/kg	[96, p. 193]
LD_{50} (mouse, oral)	1450	mg/kg	[96, p. 193]
LD_{50} (dog, oral)	> 1500	mg/kg	[96, p. 193]
LD_{50} (rabbit, oral)	1500 – 3000	mg/kg	[96, p. 193]
LD_{50} (rat, dermal)	> 1000	mg/kg	[96, p. 193]
LD_{50} (rabbit, dermal)	> 2000	mg/kg	[96, p. 193]
LC_{50} (rat, 4-h inhalation)	0.072	mg/L air	[96, p. 193]
Rabbit: irritating to skin			[96, p. 193]
Rabbit: severely irritating to eyes			[96, p. 193]
Nonmutagenic			[96, p. 193]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	6.0	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[96, p. 193]
Teratogenicity.			
Rabbit (gavage):	15	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[96, p. 193]
	30	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[96, p. 193]
Rabbit (gavage):	1	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[96, p. 193]
Chronic.			
Rat (2-year feed):	2.5	$mg\,kg^{-1}\,d^{-1}$	[96, p. 193]
Dog (2-year gavage):	15	$mg\,kg^{-1}\,d^{-1}$	[96, p. 193]

ADI: $0.03\,mg\,kg^{-1}\,d^{-1}$ [96, p. 193]

4.8. Other Compounds

Abamectin [*71751-41-2*]

LD_{50} (rat, oral)	8.7 – 12.8	mg/kg	[96, p. 3]
LD_{50} (mouse, oral)	13.6 – 23.8	mg/kg	[96, p. 3]
LD_{50} (dog, oral)	ca. 8	mg/kg	[96, p. 3]
LD_{50} (monkey, oral)	> 24	mg/kg	[96, p. 3]
LD_{50} (rat, dermal)	> 330	mg/kg	[96, p. 3]
LD_{50} (rabbit, dermal)	> 1600	mg/kg	[96, p. 3]
Rabbit: nonirritating to skin			[96, p. 3]
Rabbit: very slightly irritating to eyes			[96, p. 3]
Guinea pig: not a skin sensitizer			[96, p. 3]
Nonmutagenic			[96, p. 3]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation gavage):	0.05	$mg\,kg^{-1}\,d^{-1}$ (parental)	[96, p. 3]
	0.12	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[96, p. 3]
Teratogenicity.			
Mice (gavage):	0.05	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[96, p. 3]
	0.2	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[96, p. 3]
Rat (gavage):	1.6	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[96, p. 3]
	< 1.6	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[96, p. 3]
Rabbit (gavage):	1.0	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[96, p. 3]
Chronic.			
Rat (> 2-year feed):	2.5	$mg\,kg^{-1}\,d^{-1}$	[96, p. 3]
Mouse (94-week feed):	4	$mg\,kg^{-1}\,d^{-1}$	[96, p. 3]
Dog (52-week feed):	< 0.25	$mg\,kg^{-1}\,d^{-1}$	[96, p. 3]

ADI: $0.0001\,mg\,kg^{-1}\,d^{-1}$ [96, p. 3]

Benzoximate [*29104-30-1*]

LD_{50} (rat, oral)	5000 – 15000	mg/kg	[20, p. 113]
LD_{50} (mouse, oral)	12000 – 14500	mg/kg	[20, p. 113]
LD_{50} (rat, dermal)	> 15000	mg/kg	[20, p. 113]
LD_{50} (mouse, dermal)	> 15000	mg/kg	[20, p. 113]
NOEL/NOAEL:			
Chronic.			
Rat (2-year feed):	20	$mg\,kg^{-1}\,d^{-1}$	[20, p. 113]

Buprofezin [*69327-76-0*]

LD_{50} (rat, oral)	1635 – 2355	mg/kg	[98, p. 75]
LD_{50} (mouse, oral)	> 1000	mg/kg	[98, p. 75]
LD_{50} (hamster, oral)	> 10000	mg/kg	[98, p. 75]
LD_{50} (rabbit, oral)	> 5000	mg/kg	[98, p. 75]
LD_{50} (rat, dermal)	> 5000	mg/kg	[98, p. 75]
LC_{50} (rat, 4-h inhalation)	> 4.6	mg/L air	[98, p. 75]
Rabbit: mildly irritating to skin			[98, p. 75]
Rabbit: nonirritating to eyes			[98, p. 75]
Nonmutagenic			[98, p. 75]
NOEL/NOAEL:			
Reproduction.			
Rat (one-generation feed):	6.4	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[98, p. 75]
Teratogenicity.			
Rat (gavage):	50	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[98, p. 75]
	166	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[98, p. 75]
Rabbit (gavage):	50	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[98, p. 75]
Chronic.			
Rat (2-year feed):	0.9	$mg\,kg^{-1}\,d^{-1}$	[98, p. 75]
Mouse (2-year feed):	1.82	$mg\,kg^{-1}\,d^{-1}$	[98, p. 75]
Dog (2-year capsule):	2	$mg\,kg^{-1}\,d^{-1}$	[98, p. 75]
ADI: 0.01 $mg\,kg^{-1}\,d^{-1}$ [98, p. 75]			

Cymizaol [*61676-87-7*]

LD_{50} (rat, oral)	758	mg/kg	[20, p. 197]
LD_{50} (rat, dermal)	> 3100	mg/kg	[20, p. 197]
LC_{50} (rat, 4-h inhalation)	2.8	mg/L air	[20, p. 197]
Rabbit: slightly irritating to skin and eyes			[20, p. 197]
NOEL/NOAEL:			
Chronic.			
Rat (2-year feed):	0.5	$mg\,kg^{-1}\,d^{-1}$	[20, p. 197]
Mouse (2-year feed):	14	$mg\,kg^{-1}\,d^{-1}$	[20, p. 197]

Chinomethionate [*2439-01-2*]

LD_{50} (rat, oral)	1800 – 4800	mg/kg	[131]
LD_{50} (guinea pig, oral)	1500	mg/kg	[20, p. 198]
LD_{50} (rat, dermal)	> 5000	mg/kg	[20, p. 198]
LC_{50} (rat, 4-h inhalation)	3.0	mg/L air	[20, p. 198]
Rabbit: slightly irritating to skin and eyes			[20, p. 198]
Nonmutagenic			[102, p. 27]
NOEL/NOAEL:			
Reproduction.			
Rat (one-generation feed):	ca. 1	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[102, p. 27]
Teratogenicity.			
Rat (gavage):	25	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[102, p. 27]
Rabbit (gavage):	30	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[102, p. 27]
Chronic.			
Rat (2-year feed):	0.6	$mg\,kg^{-1}\,d^{-1}$	[102, p. 27]
Mouse (21-month feed):	16 – 21	$mg\,kg^{-1}\,d^{-1}$	[102, p. 27]
Dog (one-year feed):	0.6	$mg\,kg^{-1}\,d^{-1}$	[102, p. 27]
ADI: 0.006 $mg\,kg^{-1}\,d^{-1}$ [102, p. 27]			

Clofentezine [*74115-24-5*]

LD_{50} (rat, oral)	> 3200	mg/kg	[115, p. 17]
LD_{50} (mouse, oral)	> 3200	mg/kg	[115, p. 17]
LD_{50} (hamster, oral)	> 3200	mg/kg	[115, p. 17]
LD_{50} (dog, oral)	> 2000	mg/kg	[115, p. 17]
LD_{50} (guinea pig, oral)	> 1500	mg/kg	[115, p. 17]
LD_{50} (rat, dermal)	> 1332	mg/kg	[115, p. 17]
LC_{50} (rat, 6-h inhalation)	> 9.08	mg/L air	[115, p. 17]
Rabbit: mildly irritating to skin and eyes			[115, p. 17]
Guinea pig: not a skin sensitizer			[115, p. 17]
Nonmutagenic			[115, p. 17]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	ca. 2.7	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[115, p. 17]
Teratogenicity.			
Rat (gavage):	320	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[115, p. 17]
	1280	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[115, p. 17]
Rabbit (gavage):	250	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[115, p. 17]
	1000	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[115, p. 17]
Chronic.			
Rat (118-week feed):	2	$mg\,kg^{-1}\,d^{-1}$	[115, p. 17]
Mouse (105-week feed):	5	$mg\,kg^{-1}\,d^{-1}$	[115, p. 17]
Dog (52-week feed):	1.2	$mg\,kg^{-1}\,d^{-1}$	[115, p. 17]

ADI: $0.02\,mg\,kg^{-1}\,d^{-1}$ [115, p. 17]

Endusolfan [*115-29-7*]

LD_{50} (rat, oral)	70 – 110	mg/kg	[20, p. 459]
LD_{50} (dog, oral)	77	mg/kg	[20, p. 459]
LD_{50} (hamster, oral)	118	mg/kg	[132]
LD_{50} (rat, dermal)	500	mg/kg (female)	[20, p. 459]
	> 4000	mg/kg (male)	[20, p. 459]
LD_{50} (rabbit, dermal)	359	mg/kg	[20, p. 459]
LD_{50} (guinea pig, dermal)	1000	mg/kg	[132]
LC_{50} (rat, 4-h inhalation)	0.0345 – 0.913	mg/L air (male)	[107, p. 95]
Guinea pig: not a skin sensitizer			[107, p. 95]
Nonmutagenic			[107, p. 95]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	1.0	$mg\,kg^{-1}\,d^{-1}$ (parental)	[107, p. 95]
	6.0	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[107, p. 95]
Teratogenicity.			
Rat (gavage):	0.66	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[107, p. 95]
	2.0	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[107, p. 95]
Rabbit (gavage):	0.7	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[107, p. 95]
	1.8	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[107, p. 95]
Chronic.			
Rat (2-year feed):	0.6 – 0.7	$mg\,kg^{-1}\,d^{-1}$	[107, p. 95]
Mouse (2-year feed):	∼ 0.9	$mg\,kg^{-1}\,d^{-1}$	[107, p. 95]
Dog (one-year feed):	∼ 0.6	$mg\,kg^{-1}\,d^{-1}$	[107, p. 95]

ADI: $0.006\,mg\,kg^{-1}\,d^{-1}$ [107, p. 95]

Dienochlor [*2227-17-0*]

LD_{50} (rat, oral)	> 5000	mg/kg	[20, p. 385]
LD_{50} (rat, dermal)	> 2000	mg/kg	[20, p. 385]
LD_{50} (rabbit, dermal)	> 3160	mg/kg	[20, p. 385]
LD_{50} (rat, 4-h inhalation)	0.08	mg/L air	[20, p. 385]
Rabbit: mildly irritating to eyes and skin			[20, p. 385]
Guinea pig: not a skin sensitizer			[20, p. 385]

Fenazaquin [*120928-09-8*]

LD_{50} (rat, oral)	134 – 138	mg/kg	[20, p. 506]
LD_{50} (mouse, oral)	1480 – 2449	mg/kg	[20, p. 506]
LD_{50} (rabbit, dermal)	> 5000	mg/kg	[20, p. 506]
LC_{50} (rat, 4-h inhalation)	1.9	mg/L air	[20, p. 506]
Rabbit: slightly irritating to eyes			[20, p. 506]
Rabbit: nonirritating to skin			[20, p. 506]
Guinea pig: not a skin sensitizer			[20, p. 506]
Nonmutagenic			[20, p. 506]
Not teratogenic or carcinogenic			[20, p. 506]

ADI: $0.005\,mg\,kg^{-1}\,d^{-1}$ [20, p. 506]

Fenpyroximate [*111812-58-9*]

LD_{50} (rat, oral)	245 – 480	mg/kg	[133]
LD_{50} (mouse, oral)	440 – 520	mg/kg	[133]
LD_{50} (rat, dermal)	> 4000	mg/kg (female)	[134]
LC_{50} (rat, 4-h inhalation)	0.0002 – 0.0003	mg/L air	[133]
Rabbit: nonirritating to skin			[134]
Rabbit: slightly irritating to eyes			[134]
Nonmutagenic			[133]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	2.0	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[133]
Teratogenicity.			
Rat (gavage):	25	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[133]
Rabbit (gavage):	2.5	$mg\,kg^{-1}\,d^{-1}$ (maternal)	[133]
	> 5	$mg\,kg^{-1}\,d^{-1}$ (developmental)	[133]
Subchronic.			
Rat (13-week feed):	1.3	$mg\,kg^{-1}\,d^{-1}$	[133]
Dog (13-week feed):	2	$mg\,kg^{-1}\,d^{-1}$	[133]
Chronic.			
Rat (2-year feed):	1.0	$mg\,kg^{-1}\,d^{-1}$	[133]
Mouse (18-month feed):	9.5	$mg\,kg^{-1}\,d^{-1}$	[133]
Dog (one-year feed):	5.0	$mg\,kg^{-1}\,d^{-1}$	[133]
ADI: 0.01 $mg\,kg^{-1}\,d^{-1}$ [133]			

Flucycloxuron [*94050-52-9*]

LD_{50} (rat, oral)	> 5000	mg/kg	[20, p. 562]
LD_{50} (rat, dermal)	> 2000	mg/kg	[20, p. 562]
LC_{50} (rat, 4-h inhalation)	3.3	mg/L air	[20, p. 562]
Rabbit: nonirritating to skin			[20, p. 562]
Rabbit: mildly irritating to eyes			[20, p. 562]
Nonmutagenic			[20, p. 562]
Nonteratogenic			[20, p. 562]
Noncarcinogenic			[20, p. 562]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	ca. 10	$mg\,kg^{-1}\,d^{-1}$	[20, p. 562]
Chronic.			
Rat (2-year feed):	ca. 6	$mg\,kg^{-1}\,d^{-1}$	[20, p. 562]

Flufenoxuron [*101463-69-8*]

LD_{50} (rat, oral)	> 3000	mg/kg	[20, p. 568]
LD_{50} (rat, dermal)	> 2000	mg/kg	[20, p. 568]
LD_{50} (mouse, dermal)	> 2000	mg/kg	[20, p. 568]
LC_{50} (rat, 4-h inhalation)	5	mg/L air	[20, p. 568]
Rabbit: nonirritating to skin and eyes			[20, p. 568]
NOEL/NOAEL:			
Subchronic.			
Rat (90-day feed):	ca. 3.3	$mg\,kg^{-1}\,d^{-1}$	[20, p. 568]
Mouse (90-day feed):	ca. 7.1	$mg\,kg^{-1}\,d^{-1}$	[20, p. 568]
Dog (one-year feed):	ca. 2.5	$mg\,kg^{-1}\,d^{-1}$	[20, p. 568]

Hezythiazox [*78587-05-0*]

LD_{50} (rat, oral)	> 5000	mg/kg	[98, p. 265]
LD_{50} (mouse, oral)	> 5000	mg/kg	[98, p. 265]
LD_{50} (dog, oral)	> 5000	mg/kg	[98, p. 265]
LD_{50} (rat, dermal)	> 50000	mg/kg	[98, p. 265]
LC_{50} (rat, 4-h inhalation)	> 2.0	mg/L air	[98, p. 265]
Rabbit: nonirritating to skin			[98, p. 265]
Rabbit: slightly irritating to eyes			[98, p. 265]
Guinea pig: not a skin sensitizer			[98, p. 265]
Nonmutagenic			[98, p. 265]
NOEL/NOAEL:			
Reproduction.			
Rat (2-generation feed):	4.22 – 5.34	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[98, p. 265]
Teratogenicity.			
Rat (gavage):	240	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[98, p. 265]
Rabbit (gavage):	360	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[98, p. 265]
Chronic.			
Rat (2-year feed):	3.2 – 4.02	$mg\,kg^{-1}\,d^{-1}$	[98, p. 265]
Mouse (2-year feed):	< 6.7	$mg\,kg^{-1}\,d^{-1}$	[98, p. 265]
Dog (one-year feed):	2.87 – 3.17	$mg\,kg^{-1}\,d^{-1}$	[98, p. 265]
ADI: 0.03 $mg\,kg^{-1}\,d^{-1}$ [98, p. 265]			

Lufenuron [*103055-0-8*]

LD_{50} (rat, oral)	> 2000	mg/kg	[20, p. 753]
LD_{50} (rat, dermal)	> 2000	mg/kg	[20, p. 753]
LC_{50} (rat, 4-h inhalation)	> 2.35	mg/L air	[20, p. 753]
Rabbit: nonirritating to skin and eyes			[20, p. 753]
Guinea pig: not a skin sensitizer			[20, p. 753]
Nonmutagenic			[20, p. 753]
NOEL/NOAEL: *Chronic.*			
Rat (2-year feed):	2.0	$mg\,kg^{-1}\,d^{-1}$	[20, p. 753]

Propargite [*2312-35-8*]

LD_{50} (rat, oral)	~ 2800	mg/kg	[130, p. 403]
LD_{50} (rabbit, oral)	311	mg/kg	[130, p. 403]
LD_{50} (rabbit, dermal)	4000	mg/kg	[130, p. 403]
LC_{50} (rat, 4-h inhalation)	0.89	mg/L air	[130, p. 403]
Rabbit: severely irritating to skin and eyes			[130, p. 403]
Guinea pig: not a skin sensitizer (guinea pig)			[130, p. 403]
NOEL/NOAEL: *Reproduction.*			
Rat (3-generation feed):	15	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)	[130, p. 403]
Teratogenicity.			
Rat (gavage):	100	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)	[130, p. 403]
Chronic.			
Rat (2-year feed):	15	$mg\,kg^{-1}\,d^{-1}$	[130, p. 403]
Dog (one-year feed):	22	$mg\,kg^{-1}\,d^{-1}$	[130, p. 403]

ADI: 0.15 $mg\,kg^{-1}\,d^{-1}$ [130, p. 403]

Pyridaben [*96489-71-3*]

LD_{50} (rat, oral)	820 – 1350	mg/kg	[20, p. 1061]
LD_{50} (mouse, oral)	383 – 424	mg/kg	[20, p. 1061]
LD_{50} (rat, dermal)	> 2000	mg/kg	[20, p. 1061]
LD_{50} (rabbit, dermal)	> 2000	mg/kg	[20, p. 1061]
LC_{50} (rat, 4-h inhalation)	0.62 – 0.66	mg/L air	[20, p. 1061]
Rabbit: nonirritating to skin and eyes			[20, p. 1061]
Guinea pig: not a skin sensitizer (guinea pig)			[20, p. 1061]
Nonmutagenic			[20, p. 1061]
NOEL/NOAEL: *Chronic.*

1. Introduction

Acetaldehyde (ethanal), CH_3CHO [*75-07-0*], was observed in 1774 by Scheele during reaction of black manganese dioxide and sulfuric acid with alcohol. Its constitution was explained in 1835 by Liebig who prepared pure acetaldehyde by oxidation of ethanol with chromic acid and designated this product "aldehyde," a contraction of the term "alcohol dehydrogenatus."

Acetaldehyde is a mobile, low-boiling, highly flammable liquid with a pungent odor. Because of its high chemical reactivity, acetaldehyde is an important intermediate in the production of acetic acid, acetic anhydride, ethyl acetate, peracetic acid, butanol, 2-ethylhexanol, pentaerythritol, chlorinated acetaldehydes (chloral), glyoxal, alkyl amines, pyridines, and other chemicals. The first commercial application was the production of acetone via acetic acid between 1914 and 1918 in Germany (Wacker-Chemie and Hoechst) and in Canada (Shawinigan).

Acetaldehyde is an intermediate in the metabolism of plant and animal organisms, in which it can be detected in small amounts. Larger amounts of acetaldehyde interfere with biological processes. As an intermediate in alcoholic fermentation processes it is present in small amounts in all alcoholic beverages, such as beer, wine, and spirits. Acetaldehyde also has been detected in plant juices and essential oils, roasted coffee, and tobacco smoke.

Commercial production processes include dehydrogenation or oxidation of ethanol, addition of water to acetylene, partial oxidation of hydrocarbons, and direct oxidation of ethylene. In the 1970s, the world capacity of this last process, the Wacker-Hoechst direct oxidation, increased to over 2×10^6 t/a. However, the impor-

tance of acetaldehyde as an organic intermediate is now steadily decreasing, because new processes for some acetaldehyde derivatives have been developed, such as the oxo process for butanol and 2-ethylhexanol and the Monsanto process for acetic acid. In the future, new processes for acetic anhydride (Halcon, Eastman, Hoechst), for vinyl acetate (Halcon), and for alkyl amines (from ethanol) will diminish the use of acetaldehyde as a starting material.

2. Physical Properties

Acetaldehyde, C_2H_4O, M_r 44.054, is a colorless liquid with a pungent, suffocating odor that is slightly fruity when diluted.

bp at 101.3 kPa	20.16 °C
mp	–123.5 °C
Critical temperature t_{crit}	181.5 °C
other values	187.8 °C [12], 195.7 °C [13]
Critical pressure p_{crit}	6.44 MPa
other values	5.54 MPa [12], 7.19 MPa [13]
Relative density	$d_4^t = 0.8045 - 0.001325 \cdot t$ (t in °C) [3]
Refractive index	$n_D^t = 1.34240 - 0.0005635 \cdot t$ (t in °C) [14]
Molar volume of the gas	
at 101.3 kPa and 20.16 °C	23.40 L/mol
at 25.0 °C	23.84 L/mol

For dependence on T (293.32 – 800 K) and p (0.1 – 30 MPa), see [15].

Specific volume of the vapor	
at 20.16 °C	0.531 m^3/kg
at 25.0 °C	0.541 m^3/kg
Vapor density (air = 1)	1.52

Vapor pressure

t, °C	−20	−0.27	5.17	14.76	50	100
p, kPa	16.4	43.3	67.6	82.0	279.4	1014.0

Cubic expansion coefficient per K (0 – 20 °C)	0.00169
Heat of combustion of liquid at constant p	1168.79 (1166.4 [12]) kJ/mol
Heat of solution in water (infinite dilution)	17 906 J/mol
Latent heat of fusion	3246.3 J/mol
Latent heat of vaporization at 20.2 °C	25.73 kJ/mol
other values	27.2 [21], 30.41, 27.71 [12], 26.11 [22] kJ/mol

For dependence on temperature (nonlinear) between -80 °C (32.46 kJ/mol) and 182 °C (0 kJ/mol), see [17].

Heat of formation ΔH from the elements at 25 °C for gaseous acetaldehyde −166.47 (−166.4 [21]) kJ/mol

For dependence of heat of formation for gaseous and liquid acetaldehyde, and enthalpy of vaporization on temperature up to 800 K and 30 MPa, see [15].

Gibbs free energy of formation ΔG from elements	
at 25 °C for gaseous acetaldehyde	−133.81 kJ/mol
other values	133.72 [12], 132.9 [21] kJ/mol
Entropy for gaseous acetaldehyde	
at 25 °C	265.9 J mol^{-1} K^{-1}
Entropy for liquid acetaldehyde	
at 20.16 °C	172.9 J mol^{-1} K^{-1}
Entropy of vaporization	
at 20.16 °C	91.57 J mol^{-1} K^{-1}
First ionization potential	10.5 eV
Dissociation constant at 0 °C	0.7×10^{-14} mol/L ($H_3CCHO^- H_2CCHO + H^+$)

For the second virial coefficient of the equation of state for gaseous acetaldehyde at 31 °C, 66 °C, and 85 °C, see [23].

Acetaldehyde is completely miscible with water and most organic solvents. It forms no azeotrope with water, methanol, ethanol, acetone, acetic acid, or benzene. Binary azeotropes are formed with butane (*bp* −7 °C, 84 wt % of butane) and diethyl ether (*bp* 18.9 °C, 23.5 wt % of ether).

Other Physical Data. Compressibility and viscosity at higher pressure are given in [24], vapor pressure of aqueous acetaldehyde solutions in [25]. For solubility of carbon dioxide, acetylene, and nitrogen in acetaldehyde, see [11]; for freezing points of aqueous acetaldehyde solutions, see [11]; for vapor – liquid equilibria of binary systems of acetaldehyde with water, ethanol, acetic acid, and ethylene oxide, see [26, pp. 392, 561, 565, and 570], with vinyl acetate, see [27].

Safety Data. Flash point (Abel – Pensky; DIN 51 755; ASTM 56 – 70) −20 °C (−40 °C according to the safety regulations of the Berufsgenossenschaft der Chemischen Industrie, Federal Republic of Germany). Ignition temperature (DIN 51 794; ASTM D 2155 – 66) 140 °C; for ignition retardation when injected into a hot air stream, see [28]. Explosive limits in air: 4 – 57 vol %; for influence of pressure on explosive limits, see [29].

3. Chemical Properties and Uses

Acetaldehyde is a highly reactive compound showing all of the typical aldehyde reactions as well as those of an alkyl group in which hydrogen atoms are activated by the carbonyl group in the α position. When heated above 420 °C acetaldehyde decomposes into methane and carbon monoxide.

3.1. Addition Reactions

With water, acetaldehyde forms an unstable hydrate; isolable solid hydrates are known only with chlorinated acetaldehydes. *Alcohols* add to acetaldehyde giving hemiacetals, which form acetals (→ Aldehydes, Aliphatic and Araliphatic) with additional alcohol in the presence of acids by removal of water. Diols give cyclic acetals; for example, 2-methyl-1,3-dioxolane is obtained from ethylene glycol and acetaldehyde, and 2-methyl-1,3-dioxane from 1,3-propanediol.

Aqueous *sodium bisulfite* solution and acetaldehyde give a crystalline adduct from which acetaldehyde can be liberated. Dry *ammonia* forms crystalline acetaldehyde ammonia. Acetaldehyde and *hydrocyanic acid* react to give lactonitrile (α-hydroxypropionitrile), a possible intermediate in acrylonitrile production [30].

Acetaldehyde reacts with *acetic anhydride* to give ethylidene diacetate, an intermediate in the vinyl acetate process of Celanese Corp. [31] (→ Vinyl Esters).

3.2. Derivatives of Aldol Addition

Two molecules of acetaldehyde combine in the presence of alkaline catalysts or dilute acids at room temperature or with moderate heating to form acetaldol [*107-89-1*], $CH_3CH(OH)CH_2CHO$. At increased temperatures, water is cleaved easily from this acetaldol, forming crotonaldehyde (→ Aldehydes, Aliphatic and Araliphatic). Further condensation under more stringent conditions to form aldehyde resins (e.g., synthetic shellac) now has no industrial importance.

Urea and acetaldehyde condense in the presence of H_2SO_4 to form crotonylidenediurea (6-methyl-4-ureidohexahydropyrimidin-2-one [*1129-42-6*]), which is used as a long-term nitrogen fertilizer (→ Fertilizers).

Acetaldehyde is also an intermediate in the butadiene synthesis starting from acetylene and proceeding via acetaldol and its hydrogenation product, 1,3-butanediol [32]. This process was introduced around 1918 and is still carried out on a commercial scale in some Eastern European countries.

Acrolein is obtained by aldol condensation of acetaldehyde and formaldehyde and subsequent water elimination, analogous to the formation of crotonaldehyde. This method is also without commercial importance today, whereas the production of pentaerythritol from acetaldehyde and a fourfold amount of formaldehyde in the presence of $Ca(OH)_2$ or NaOH is very important industrially (→ Alcohols, Polyhydric).

3.3. Reaction with Nitrogen Compounds

With primary amines, Schiff bases, $CH_3CH{=}NR$, are formed. Nitrogen compounds such as hydroxylamine, hydrazine, phenylhydrazine, and semicarbazide react with acetaldehyde to give easily crystallizable compounds

that are used for the analytical determination and characterization of aldehydes (semicarbazone, *mp* 162 – 163 °C; *p*-nitrophenylhydrazone, *mp* 128.5 °C; 2,4-dinitrophenylhydrazone, *mp* 168 °C; oxime, *mp* 47 °C). Many other aldehydes and ketones can be characterized in the same way because their analogous derivatives generally have sharp melting points.

The synthesis of pyridine and pyridine derivatives is of increasing importance. 5-Ethyl-2-methylpyridine is obtained in the presence of fluoride ions by the reaction of aqueous ammonia with acetaldehyde (or with paraldehyde, which slowly releases the monomer). In the added presence of formaldehyde or acrolein, mixtures of pyridine and alkylpyridines form (→ Pyridine and Pyridine Derivatives).

3.4. Oxidation

The major part of the acetaldehyde produced commercially is used for manufacturing acetic acid by oxidation with oxygen or air (→ Acetic Acid). Acetaldehyde monoperacetate is formed as an intermediate and decomposes into peracetic acid and acetaldehyde at elevated temperatures and in the presence of catalytic amounts of iron or cobalt salts. In the presence of Mn^{2+} salts, acetic acid is obtained from acetaldehyde monoperacetate, and in the presence of Co^{2+} and Cu^{2+} salts, acetic anhydride can be formed.

Oxidation with nitric acid gives glyoxal (→Glyoxal and → Glyoxylic Acid). Halogenated acetaldehydes are prepared by halogenation.

Mono-, di-, and trichloroacetaldehydes (→ Chloroacetaldehydes) and tribromoacetaldehyde (bromal) are useful for producing insecticides (e.g., DDT, DDD), pharmaceuticals, and dyes.

3.5. Reduction

Acetaldehyde is hydrogenated readily to ethanol. Prior to 1939, that is, before petrochemically produced ethylene became available in Europe, this reaction was used industrially to produce ethanol from acetaldehyde and, therefore, from acetylene.

Mono-, di-, and triethylamine [*75-04-7*], [*109-89-7*], [*121-44-8*] can be produced from acetaldehyde, ammonia, and hydrogen in the presence of a hydrogenation catalyst [33] (→ Amines, Aliphatic).

3.6. Miscellaneous Reactions

The Tishchenko reaction of acetaldehyde gives the commercially important solvent ethyl acetate (→ Acetic Acid); it is catalyzed by aluminum alcoholate.

As a "radical trapping agent," acetaldehyde is used to control chain length in the polymerization of vinyl compounds.

Oligomers of acetaldehyde are treated in Chapter 8.

3.7. Consumption

The consumption of acetaldehyde has changed during the last few years. Since 1993 in the USA, acetaldehyde is no longer used for the production of acetic acid, butanol, or 2-ethylhexanol, which are now produced by other routes (Table 1). The consumption of acetaldehyde for some other chemicals like peracetic acid or pyridine bases is increasing.

4. Production

Raw materials that have been used for the production of acetaldehyde are:

1) Ethanol from fermentation of carbohydrates or from hydration of ethylene
2) Acetylene
3) Ethylene
4) Lower hydrocarbons
5) Carbon monoxide and hydrogen
6) Methanol

Table 1. Consumption of acetaldehyde (10^3 t) in 2003 [56]

Product	USA	Mexico	W. Europe	Japan	Total
Acetic acid/acetic anhydride		11	89	47	147
Acetate esters	35	8	54	224	321
Pentaerythritol	26		43	11	80
Pyridine and pyridine bases	73		10	*	83
Peracetic acid	23			*	23
1,3-Butylene glycol	14			*	14
Others	5	3	10	80	98
Total	176	22	206	362	766

* Included in others (glyoxal/glyoxalic acid, crotonaldehyde, lactic acid, *n*-butanol, 2-ethylhexanol).

The economy of the commercial processes depends essentially upon prices and the availability of raw materials. In highly industrialized countries maintaining high prices for ethanol by fiscal measures or where petrochemical ethanol was not available, as in Germany or Japan before 1939, acetylene was the favored starting material for acetaldehyde. The acetylene process is still operated in some Eastern European countries and also by companies where cheap acetylene is available. Petrochemically produced ethanol, however, was the favored raw material in the other countries, whereas ethanol made by fermentation was and still is used on a small scale in countries with less chemical industry.

In Western countries, including Japan, all these processes have now been almost completely replaced by the direct oxidation process developed in the late 1950s by Wacker-Chemie and Hoechst. This is because ethylene is available at a lower price than acetylene.

Even the two-stage processes using ethanol from ethylene as starting material are no longer competitive because of the decreasing importance of acetaldehyde as an organic intermediate (see Chap. 7).

Generally, all processes based on acetylene, ethylene, and ethanol are more selective than the oxidation of saturated hydrocarbons. This is because, in the latter case, other oxidation products are formed in addition to acetaldehyde. Because of the great expense of separating the product mixture, such processes are economical only in large units and when all main and secondary products obtained in the process are utilized.

4.1. Production from Ethanol

For the production of acetaldehyde, ethanol can either be dehydrogenated or oxidized in the presence of oxygen. Between 1918 and 1939, dehydrogenation took precedence over oxidation because of the simultaneous production of hydrogen. Later, however, the catalytic vapor-phase oxidation of ethanol became the preferred process, probably because of the long catalyst life and the possibility of recovering energy.

Dehydrogenation of Ethanol. In the first work on ethanol dehydrogenation, published in 1886, ethanol was passed through glass tubes at 260 °C.

$$CH_3CH_2OH\ (l) \rightarrow CH_3CHO\ (l) + H_2\ (g)$$
$$\Delta H = +82.5\ \text{kJ/mol}$$

Improved yields are obtained in the presence of catalysts such as platinum, copper, or oxides of zinc, nickel, or cobalt. In later patents, zinc and chromium catalysts [34], oxides of rare earth metals [35], and mixtures of copper and chromium oxides [36] have been reported. The lowest amounts of decomposition products are obtained using copper catalysts. Frequent regeneration of the catalysts is required, however.

Process Description. Ethanol vapor is passed at 260 – 290 °C over a catalyst consisting of copper sponge or copper activated with chromium oxide in a tubular reactor [37]. A conversion of 25 – 50 % per run is obtained. By washing with alcohol and water, acetaldehyde and ethanol are separated from the exhaust gas, which is mainly hydrogen. Pure acetaldehyde is obtained by distillation; the ethanol is separated from water and higher-boiling products by

distillation and flows back to the reactor. The final acetaldehyde yield is ca. 90 %. Byproducts include butyric acid, crotonaldehyde, and ethyl acetate.

Oxidation of Ethanol. Oxidation of ethanol is the oldest and the best laboratory method for preparing acetaldehyde. In the commercial process, ethanol is oxidized catalytically with oxygen (or air) in the vapor phase.

$$CH_3CH_2OH\,(g) + 1/2O_2\,(g) \rightarrow CH_3CHO\,(l) + H_2O\,(l) \qquad \Delta H = -242.0\,\mathrm{kJ/mol}$$

Copper, silver, and their oxides or alloys are the most frequently used catalysts [38].

For an example of a simultaneous oxidation – dehydrogenation process, see [39].

Veba-Chemie Process (Fig. 1). Ethanol is mixed with air and passed over a silver catalyst at 500 – 650 °C (c). The temperature depends on the ratio of alcohol to air and the flow rate of the gas through the catalyst. Alcohol conversion varies between 50 and 70 % and the yield is between 97 and 99 % depending on the reaction conditions. Acetaldehyde and unconverted alcohol are removed from the waste gas by washing with cold alcohol (e) and separated by fractional distillation (h); after concentration the alcohol returns to the reactor. Heat formed in the reaction is utilized for steam production using a waste-heat recovery system immediately after the reaction zone.

Figure 1. Acetaldehyde production by the Veba-Chemie process
a) Air compressor; b) Heat recovery system; c) Reactor; d) Cooler; e) Waste-gas scrubber; f) Washing-alcohol and return pump; g) Cooler; h) Acetaldehyde rectification

The waste gas consists mainly of nitrogen, hydrogen, methane, carbon monoxide and carbon dioxide; it is burned as lean gas with low calorific value in steam generators. Small amounts of acetic acid are obtained as a byproduct.

4.2. Production from Acetylene

The most important catalysts for the industrial water addition (hydration) are mercury compounds:

$$C_2H_2\,(g) + H_2O\,(l) \xrightarrow[H_2SO_4]{Hg^{2+}} CH_3CHO\,(l)\ \Delta H = -138.2\,\mathrm{kJ/mol}$$

This method only succeeds industrially when the polymerization and condensation products of acetaldehyde formed in the acid medium are eliminated. To achieve this, the Consortium für elektrochemische Industrie in 1912 proposed a process using excess acetylene at an elevated temperature and removing the acetaldehyde product immediately from the reaction liquid. At the same time, the heat of reaction is removed by distilling an appropriate amount of water. Secondary reactions, such as the oxidation of acetaldehyde to form acetic acid and carbon dioxide, result in reduction of Hg^{2+} to metallic mercury. In Western countries, acetaldehyde production from acetylene has now been discontinued.

Wet Oxidation Process (Hoechst). The wet oxidation process avoided direct handling of the toxic mercury compounds. It was operated, among others, by Wacker-Chemie until the changeover to ethylene as the starting material in 1962.

In this method, iron(III) sulfate is added to reoxidize the mercury metal to the mercury(II) salt, thus ensuring sufficient concentrations of active catalyst. The acetylene reacts at 90 – 95 °C with the aqueous catalyst solution; between 30 and 50 % of the injected acetylene reacts in one run. The gas emerging from the reactor is cooled; mainly water and traces of mercury are separated and returned to the reactor. Acetaldehyde and water are condensed in additional coolers and the acetaldehyde finally is washed

out with water from the cycle gas which has been cooled to 25 – 30 °C. An 8 – 10 % aqueous acetaldehyde solution is obtained. Nitrogen is introduced with the feed gas while carbon dioxide is formed as a byproduct; to avoid excessive accumulation, these gases are removed by withdrawing a small stream of the cycle gas. Iron(II) sulfate is formed in the reaction and is oxidized in a separate reactor with 30 % nitric acid at 95 °C. Pure acetaldehyde is obtained by fractional distillation of the aqueous solution at about 200 kPa. For further details of this process, see [40].

Chisso Process [41]**.** The Chisso process also uses sulfuric acid/mercury sulfate solution as a catalyst. The acetylene reacts completely with the catalyst solution at 68 – 78 °C and a gauge pressure of 140 kPa. A combination of pressure and vacuum process stages at low temperature and without excess acetylene is used; pure acetaldehyde can be isolated and distilled by utilizing the heat of the reaction. As in the Hoechst process, the catalyst can be regenerated with nitric acid. Production of acetaldehyde by this method was discontinued at Chisso Corp. more than a decade ago.

Production via Vinyl Ether. Reppe at BASF developed the process using vinyl ether [40]; it was operated in a pilot plant between 1939 and 1945. The use of toxic mercury compounds is avoided altogether. Methanol is added to acetylene at 150 – 160 °C and 1600 kPa in the presence of potassium hydroxide to form methyl vinyl ether [*107-25-5*]. The methyl vinyl ether is then hydrolyzed with dilute acid:

$$C_2H_2 + CH_3OH \xrightarrow{KOH} CH_3OCH{=}CH_2 \xrightarrow{H_2O,\,H^+} CH_3OH + CH_3CHO$$

Production via Ethylidene Diacetate. Addition of acetic acid to acetylene in the presence of mercury(II) salts yields ethylidene diacetate [*542-10-9*], $CH_3CH(OCOCH_3)_2$, which decomposes into acetaldehyde and acetic anhydride at 130 – 145 °C in the presence of acid catalysts (e.g., $ZnCl_2$). This process was developed by the Societe Chimique des Usines du Rhône on an industrial scale in 1914 but is now without importance.

4.3. Production from Ethylene

Ethylene is now the most important starting material for the production of acetaldehyde. Most of the present capacity works by the direct oxidation of ethylene (Wacker process).

4.3.1. Direct Oxidation of Ethylene

This process was developed between 1957 and 1959 by Wacker-Chemie and Hoechst [42]. Formally, the reaction proceeds as follows:

$$C_2H_4 + 1/2O_2 \rightarrow CH_3CHO \quad \Delta H = -244\ \mathrm{kJ/mol}$$

An aqueous solution of $PdCl_2$ and $CuCl_2$ is used as catalyst. Acetaldehyde formation had already been observed in the reaction between ethylene and aqueous palladium chloride. This reaction is almost quantitative:

$$C_2H_4 + PdCl_2 + H_2O \rightarrow CH_3CHO + Pd + 2HCl$$

In the Wacker-Hoechst process, metallic palladium is reoxidized by $CuCl_2$, which is then regenerated with oxygen:

$$Pd + 2CuCl_2 \rightarrow PdCl_2 + 2CuCl$$

$$2CuCl + 1/2O_2 + 2HCl \rightarrow 2CuCl_2 + H_2O$$

Therefore only a very small amount of $PdCl_2$ is required for the conversion of ethylene. The reaction of ethylene with palladium chloride is the rate-determining step.

One- and two-stage versions of the process are on stream. In the *one-stage method*, an ethylene – oxygen mixture reacts with the catalyst solution. During the reaction a stationary state is established in which "reaction" (formation of acetaldehyde and reduction of $CuCl_2$) and "oxidation" (reoxidation of CuCl) proceed at the same rate. This stationary state is determined by the degree of oxidation of the catalyst, as expressed by the ratio $c_{Cu^{2+}} / (c_{Cu^{2+}} + c_{Cu^{+}})$. In the *two-stage process* the reaction is carried out with ethylene and then with oxygen in two separate reactors. The catalyst solution is alternately reduced and oxidized. At the same time the degree of oxidation of the catalyst changes alternately. Air is used instead of pure oxygen for the catalyst oxidation.

Reaction Mechanism. The first step of the reaction is the complexation of ethylene to give a palladium ethylene complex

$$[PdCl_4]^{2-} + H_2C = CH_2 \rightleftharpoons [(C_2H_4)\,PdCl_3]^- + Cl^-$$

Kinetic studies of this reaction show that chloride ions have a inhibiting effect which is explained by the following substitution of a further chloride ligand by a water molecule:

$$[(C_2H_4)\,PdCl_3]^- + H_2O \rightleftharpoons [(C_2H_4)\,PdCl_2\,(H_2O)] + Cl^-$$

Dissociation of hydrogen ions explains the inhibiting effect of acids:

$$[(C_2H_4)\,PdCl_2\,(H_2O)] \rightleftharpoons [(C_2H_4)\,PdCl_2\,(OH)]^- + H^+$$

It is assumed that the hydroxyl complex has the *trans* geometry. Evidence for the *trans – cis* isomerisation of this complex was revealed by a detailed kinetic study of the reaction. π-Bonded ethylene ligands in the *trans* position weaken the metal – chlorine bonds, so that the chloro ligand can be easily substituted by a water molecule from which a hydrogen ion dissociates.

$$trans\text{-}[(C_2H_4)\,PdCl_2\,(OH)]^- + H_2O \rightleftharpoons [(C_2H_4)\,PdCl(OH)_2]^- + H^+ + Cl^-$$

The OH^- ligand in the *trans* position is replaced by a Cl^- ion, leading to a *cis* complex:

$$[(C_2H_4)\,PdCl(OH)_2]^- + H^+ + Cl^- \rightleftharpoons cis\text{-}[(C_2H_4)\,PdCl_2\,(OH)]^- + H_2O$$

The next reaction step is the formation of a σ-bonded hydroxyethylpalladium species. This reaction has been regarded as a *cis* ligand insertion reaction in which the OH^- ligand attacks the π-bonded olefin:

$$cis\text{-}[(C_2H_4)\,PdCl_2\,(OH)]^- \rightleftharpoons [HOCH_2CH_2PdCl_2]^-$$

Hydride transfer to give an α-hydroxyethylpalladium complex is followed by reductive elimination, which is the rate-determining step:

$$[HOCH_2CH_2PdCl_2]^- \rightleftharpoons [CH_3CH\,(OH)\,PdCl_2]^-$$

$$[CH_3CH\,(OH)\,PdCl_2]^- \rightarrow CH_3CHO + Pd + H^+ + 2Cl^-$$

For a detailed description, see [43]. The rate of reaction can be given by the following equation [44]:

$$\frac{-d\,c_{C_2H_4}}{d\,t} = k\,\frac{c_{PdCl_4^{2-}} \cdot c_{C_2H_4}}{c_{H^+} \cdot c_{Cl^-}^2}$$

The rate of reaction is diminished by the acid formed in the reduction of palladium chloride. This can be prevented by buffering the acid with basic copper salts (copper oxychloride, copper acetate). Reformation of the basic copper salts takes place during catalyst oxidation.

One-Stage Process (Fig. 2). Ethylene and oxygen are charged into the lower part of the reaction tower (a); the catalyst is circulated via the separating vessel (b) by the airlift principle and thoroughly mixed with the gas. Reaction conditions are about 130 °C and 400 kPa. An acetaldehyde – water vapor mixture, together with unconverted gas, is withdrawn from the separating vessel; from this mixture the reaction products are separated by cooling (c) and washing with water (d); unconverted gas is returned to the reactor. A small portion is discharged from the cycle gas as exhaust gas to prevent accumulation of inert gases in the cycle gas; these inert gases are either introduced as contamination of the feed gas (nitrogen, inert hydrocarbons) or formed as byproducts (carbon dioxide). A partial stream of catalyst is heated to 160 °C (m) to decompose byproducts that have accumulated in the catalyst.

Crude acetaldehyde obtained during washing of the reaction products is distilled in two stages. The first stage (g) is an extractive distillation with water in which lights ends having lower boiling points than acetaldehyde (chloromethane, chloroethane, and carbon dioxide) are separated at the top, while water and higher-boiling byproducts, such as acetic acid, crotonaldehyde, or chlorinated acetaldehydes, are withdrawn together with acetaldehyde at the bottom. In the second column (i) acetaldehyde is purified by fractional distillation.

Two-Stage Process (Fig. 3). Tubular reactors (a), (d) are used for both "reaction" and "oxidation". The gases react almost completely in the presence of the catalyst. Reaction of ethylene takes place at 105 – 110 °C and 900 – 1000 kPa. Catalyst solution containing acetaldehyde is then expanded in a flash tower (b) by reducing the pressure to atmospheric level. An acetaldehyde – water vapor mixture distills overhead while catalyst is sent via the pump (c) to the oxidation reactor (d), in which it reacts with oxy-

gen at about 1000 kPa. As oxidation and reaction are carried out separately, no high-purity starting gas is required. Generally, air is used instead of oxygen. Oxygen conversion is almost complete; the exhaust air from (e) can be used as inert gas for plant use. The oxidized catalyst solution separated from exhaust air in the separator (e) is reused for the reaction with ethylene in (a).

Acetaldehyde – water vapor mixture from the flash tower (b) is preconcentrated in column (f) to 60 – 90 % acetaldehyde by utilizing the heat of reaction. Process water discharged at the bottom of (f) is returned to the flash tower to maintain a constant catalyst concentration. A portion of the process water is used for scrubbing exhaust air (nitrogen from the "oxidation") in (i) and exhaust gas (inert gas from the "reaction") in (k) free of acetaldehyde. Scrubber water then flows to the crude aldehyde column (f).

A two-stage distillation of the crude acetaldehyde follows. In the first stage (l), low-boiling substances, such as chloromethane, chloroethane and carbon dioxide, are separated. In the second stage (o), water and higher-boiling byproducts, such as chlorinated acetaldehydes and acetic acid, are removed from acetaldehyde, and the latter is obtained in pure form overhead. Chlorinated acetaldehydes become concentrated within the column as medium-boiling substances and are discharged laterally. From

this mixture, monochloroacetaldehyde can be obtained as the hemihydrate. Residual byproducts can be returned to the catalyst for oxidative decomposition. This oxidative self-purification is supported by thermal treatment of a partial stream of catalyst at about 160 – 165 °C (regeneration, r).

When gas mixtures obtained in naphtha cracking processes are used as raw material, conventional towers are used as reactors instead of coiled pipes; So far, these processes have not been developed industrially. Such mixtures contain 30 – 40 % ethylene in addition to inert hydrocarbons and hydrogen [45].

Comparison of the Two Methods. In both one- and two-stage processes the acetaldehyde yield is about 95 % and the production costs are virtually the same. The advantage of using dilute gases in the two-stage method is balanced by higher investment costs. Both methods yield chlorinated hydrocarbons, chlorinated acetaldehydes, and acetic acid as byproducts. Generally, the choice of method is governed by the raw material and energy situations as well as by the availability of oxygen at a reasonable price.

Balance of Reaction and Side Products. The yield in both type of process is nearly the same. The balance of the two stage process is as follows:

100 parts of ethylene gives:

95 parts acetaldehyde
1.9 parts chlorinated aldehydes
1.1 parts unconverted ethylene
0.8 parts carbon dioxide
0.7 parts acetic acid
0.1 parts chloromethane
0.1 parts ethyl chloride
0.3 parts ethane, methane, crotonaldehyde and other minor side products

The chlorinated aldehydes consist of chloroacetaldehyde, dichloroacetaldehyde, trichloroacetaldehyde, and 2-chloro-2-butenal.

Process Variant. An interesting variant of the process, although so far of no technical importance, uses glycol as the reaction medium. The cyclic acetal of acetaldehyde, namely the easily hydrolyzable 2-methyl-1,3-dioloxane, is obtained. An advantage of this method is the high rate of reaction [46].

Construction Materials. During process development, serious problems have been caused by the extremely corrosive aqueous $CuCl_2 - PdCl_2$ solution. These problems have been solved in the two-stage process either by constructing parts in contact with the catalyst solution entirely from titanium or by lining those parts with the metal. In the one-stage process, the reactor is lined with acid-proof ceramic material, the tubing is made of titanium, and certain other parts are of tantalum.

Waste Air. The waste air from the oxidation process contains small amounts of unconverted ethylene, some acetaldehyde, and side products from the reaction such as ethane, chloromethane, chloroethane, and methane. In Germany the waste air must be purified of these side products to meet the criteria of TA-Luft [47]. The byproducts are oxidized over a chromium oxide catalyst. The hydrogen chloride generated is removed by washing, so that the waste air contains mainly carbon dioxide.

Wastewater. Side products of the oxidation process that enter the wastewater are acetic acid, crotonaldehyde and chlorinated aldehydes. Some of the chlorinated aldehydes are highly toxic and show high antimicrobial activity. Therefore they must be treated before entering the wastewater plant to render them biologically degradable. Cleavage of organic chlorine by alkaline hydrolysis is a possible method. If the chlorinated compounds can not be destroyed the wastewater has to be incinerated.

4.3.2. Acetaldehyde as Byproduct

Acetaldehyde is also formed in the production of vinyl acetate from ethylene or acetylene (→ Vinyl Esters). It is separated by distillation and is normally converted to acetic acid for reuse. In one version of the method starting from ethylene, vinyl acetate and acetaldehyde are obtained in a molar ratio of 1 : 1. This makes the process nearly self-sufficient in acetic acid.

4.3.3. Isomerization of Ethylene Oxide

Research was carried out on this process [48] before adopting the direct oxidation of ethylene.

Catalysts were Al_2O_3, SiO_2, and acid salts of mineral acids, such as sulfuric acid, phosphoric acid, or molybdic acid. Yields of 90 – 95 % have been reported, but the process has not gained industrial importance.

4.4. Production from C_1 Sources

Since the increases in oil price in 1973/74 and 1977, C_1 material has gained interest as a feedstock for organic chemicals and as a substitute for petrochemicals. However, for acetaldehyde production, C_1 material seems to be of minor importance because most of the classical acetaldehyde derivatives can be made from C_1 sources.

Production Directly from Synthesis Gas. Acetaldehyde is formed with low selectivity and a yield of ca. 30 % from synthesis gas, together with acetic acid, ethanol, and saturated hydrocarbons, mainly methane. Catalysts are cobalt and rhodium compounds activated by iodine compounds or magnesium chloride and supported on a silicate carrier [49]. There is so far no industrial use of this process.

Production via Methanol, Methyl Acetate, or Acetic Anhydride. *Hydroformylation of methanol* with CO/H_2 has been well known since the discovery of the oxo process [50]. It takes place in the presence of hydroformylation catalysts, such as cobalt, nickel, and iron salts (e.g., $CoBr_2$, CoI_2) or the corresponding metal carbonyls, at increased temperature (180 – 200 °C) and high pressure (30 – 40 MPa). An acetaldehyde selectivity of 80 % or more has been claimed using an iron – cobalt carbonyl or alternatively a cobalt – nickel catalyst in the presence of tertiary amines, phosphines, or nitriles as the catalyst [51, 52].

Similarly, high selectivity has been claimed for the *hydrocarbonylation of methyl acetate* with palladium or rhodium catalysts in the presence of tertiary phosphines and iodine compounds as well as cobalt – ruthenium catalysts in the presence of methyl and sodium iodides [53].

Some patents describe the formation of acetaldehyde by *reduction of acetic anhydride* with hydrogen over palladium or platinum on a carrier at low pressures and moderate temperatures [54]. If the importance of acetaldehyde as an organic intermediate were to decrease in the future as outlined in Chapter 8, this method might be of some interest for the economical production of small quantities of acetaldehyde.

4.5. Production from Hydrocarbons

Acetaldehyde is a byproduct of the production of acrolein, acrylic acid, and propene oxide from propene. It is also formed in the oxidation of saturated hydrocarbons (e.g., propane or butane) in the gas phase as operated by Celanese in the United States [55] (→ Acetic Acid).

5. Quality and Analysis

High demands on acetaldehyde purity generally are made; a typical specification is:

Color	practically colorless
Acetaldehyde	more than 99.5 wt %
Acid (as acetic acid)	less than 0.1 wt %
Water	less than 0.02 wt %
Chlorine	less than 30 mg/kg
Dry residue	less than 10 mg/kg

The *acid content* is determined directly by titration, *water content* using the Karl Fischer reagent or empirically from the cloud point of a carbon disulfide – acetaldehyde mixture, and *chlorine content* (mostly in the form of organic chlorine compounds) by combustion in a hydrogen stream and determination of the hydrochloric acid in the condensate.

6. Storage and Transportation

6.1. Storage

For storage of acetaldehyde, the national regulations must be observed. In *Germany* the ordinance on operational safety (Betriebssicherheitsverordnung) applies, under which acetaldehyde is classified as highly inflammable liquid (F+). In the *USA*, loading and storage of acetaldehyde are governed by the EPA.

In *Japan* the Fire Defense Law and the supplement "Cabinet Order for Control of Dangerous Articles" applies. According to these regulations, outer storage tanks must not be made of

copper, magnesium, silver, mercury, or alloys of these metals. They must be equipped with cooling facilities in order to keep the temperature below 15 °C, and also with an inert-gas sealing system.

For safety data, see Chapter 2.

6.2. Transportation

International Regulations. Acetaldehyde is classified as a flammable liquid. Transportation is governed by:

IMDG Code (sea transport): class 3, UN 1089, packing group I
RID (rail): class 3, UN 1089, packing group I
ADR (road): class 3, UN 1089, packing group I
ADNR (inland waterways), class 3, UN 1089, packing group I
IATA-DGR (air transportation): class 3, UN 1089, packing group I, PAC forbidden, CAC packing instruction 304, 30 L max.

National Regulations. *Germany:* GGVSE (road and rail); GGVSee (sea). *USA:* Regulations of the U.S. Department of Transportation: CFR 49.

Types and sizes of packaging and containers are recommended by the regulations mentioned above.

6.3. Other Regulations

In *Germany*, any accidental release of acetaldehyde into the air, water, or soil must be reported to the appropriate authorities according to the ordinance on operational safety (Betriebssicherheitsverordnung) or the regulations on units for storing, filling, and moving materials dangerous to water supplies (Hazardous Incident Ordinance, Störfallverordnung, 2005).

In the *United States*, a similar regulation applies according to the Comprehensive Environmental Response, Compensation, and Liability Act of 1980. Incidents must be reported to the National Response Center for Water Pollution.

In *Japan*, acetaldehyde is specified as an Offensive Odor Material by the Offensive Odor Control Law. Under this law a district of dense population is specified, for which the concentration of the material in the air is limited. The maximum level of acetaldehyde allowed at the boundary of the factory or place where acetaldehyde is handled is 0.5 ppm.

Environmental problems are dealt with by the respective national laws (see above). If acetaldehyde is highly diluted with water it can easily be degraded biologically. In higher concentrations it kills bacterial flora.

7. Economic Aspects

Today the most important production process worldwide is the direct oxidation of ethylene. In Western Europe there is also some capacity for the production of acetaldehyde by oxidation of ethanol (7 %) and hydration of acetylene (17 %). In South America the entire capacity for production of acetaldehyde is based on the oxidation of ethanol.

However, the demand for acetaldehyde worldwide has continued to decrease primarily as a result of less consumption for acetic acid manufacture, as the industry continues to move toward the more efficient methanol carbonylation process. All manufacture of acetic acid from acetaldehyde in North America has been discontinued, and in Europe significant capacity for this transformation has been permanently shut down. Acetaldehyde use for acetic acid manufacture in Asia continues but is under pressure and will decline because of the establishment of methanol carbonylation technology. Since 1995, some 360 000 t of acetaldehyde capacity has been shut down in Western Europe, and Mexico has eliminated its acetaldehyde capacity. New acetaldehyde capacity has been installed in China, but this is the only area where new capacity has been added. Further carbonylation capacity will be added between 2006 and 2008, but afterward the demand for acetaldehyde for acetic acid will eventually be phased out. Capacity in China is expected to be around 860 000 t by 2008 and is expected to remain at those levels for at least five more years.

Table 2 gives production data for acetaldehyde.

Important producers and their production capacities (10^3 t) are listed in the following [56]:

Table 2. Production of acetaldehyde (10^3 t) [56]

Year	USA	W. Europe	Mexico	Japan	China	Total
1990	283	603	190	384		1460
1995	111	668	271	395	400	1845

8. Polymers of Acetaldehyde

8.1. Paraldehyde

Paraldehyde, 2,4,6-trimethyl-1,3,5-trioxane [*123-63-7*], $C_6H_{12}O_3$, M_r 132.161, is a cyclic trimer of acetaldehyde:

Properties. Paraldehyde is colorless and has an ethereal, penetrating odor.

bp	124.35 °C
mp	12.54 °C
Critical temperature t_{crit}	290 °C
Solubility in 100 g water at 13 °C	12 g
at 75 °C	5.8 g
In the solid state, four different crystal forms exist; transition points: 230.3 K, 147.5 K, 142.7 K.	
Paraldehyde is miscible with most organic solvents.	
Density d_4^{20}	0.9923
Refractive index n_D^{20}	1.4049
Viscosity at 20 °C	1.31 mPa · s
Heat of combustion at constant pressure	3405 kJ/mol
Heat capacity c_p at 25 °C	1.947 J g^{-1} K^{-1}
Entropy (l) at 25 °C	2.190 J g^{-1} K^{-1}
Free energy (l) at 25 °C	276.4 J/g
Heat of vaporization	41.4 kJ/mol
Latent heat of melting	104.75 J/g
Heat of formation from acetaldehyde(calculated from combustion enthalpies)	−113.0 kJ/mol
The equilibrium 3 acetaldehyde ⇌ paraldehyde is 94.3 % on the paraldehyde side at 150 °C.	

Production. Paraldehyde is produced from acetaldehyde in the presence of acid catalysts, such as sulfuric acid, phosphoric acid, hydrochloric acid, or acid cation exchangers. In the homogeneous reaction, acetaldehyde is added, with stirring and cooling, to paraldehyde containing a small amount of sulfuric acid. After the addition is completed, stirring is continued for some time to establish the equilibrium; the sulfuric acid is exactly neutralized with a sodium salt, such as sodium acetate, sodium carbonate, or sodium bicarbonate; the reaction mixture is separated into acetaldehyde, water, and paraldehyde by fractional distillation [57].

For continuous production, liquid acetaldehyde at 15 – 20 °C or acetaldehyde vapor at 40 – 50 °C is passed over an acid cation exchanger [58]. Conversion is greater than 90 %. Acetaldehyde and paraldehyde are separated by distillation. For depolymerization, acetaldehyde is slowly distilled off in the presence of acid catalysts. Paraldehyde also can be decomposed in the gas phase. Catalysts are HCl, HBr, H_3PO_4, or cation exchangers. The reaction is first order. Other catalysts described in the literature are Al_2O_3, SiO_2, $ZnSO_4$, and $MgSO_4$ [59].

Uses. Paraldehyde is used in chemical synthesis as a source of acetaldehyde whereby resin formation and other secondary reactions are largely eliminated. Such synthetic reactions are, for instance, used for the production of pyridines and chlorination of chloral. Between 1939 and 1945 paraldehyde was used as a motor fuel.

8.2. Metaldehyde

Metaldehyde [*9002-91-9*], $C_8H_{16}O_4$, M_r 176.214, is the cyclic tetramer of acetaldehyde:

Properties. Metaldehyde forms tetragonal prisms, *mp* (closed capillary) 246.2 °C, sublimation temperature (decomp.) 115 °C, heat of combustion at constant volume 3370 kJ/mol.

Metaldehyde is insoluble in water, acetone, acetic acid, and carbon disulfide.

Depolymerization of metaldehyde to acetaldehyde begins at 80 °C, and is complete above 200 °C. Depolymerization takes place faster and at lower temperatures in the presence of acid catalysts, such as dilute H_2SO_4 or H_3PO_4. Metaldehyde does not show the typical acetaldehyde reactions. It is stabilized by ammonium carbonate or other weakly basic compounds which neutralize acidic potential catalysts.

Production. Metaldehyde is obtained in addition to large amounts of paraldehyde during polymerization of acetaldehyde in the presence of HBr and alkaline earth metal bromides, such as $CaBr_2$, at temperatures below 0 °C. However, yields are scarcely higher than 8 %. Yields of 14 – 20 % have been reported when working in the presence of 7 – 15 % of an aliphatic or cyclic ether at 0 – 20 °C [60]. Insoluble metaldehyde is filtered out. Acetaldehyde is then distilled from the filtrate following depolymerization of the paraldehyde and is returned to the polymerization. Recycling of the large amounts of acetaldehyde results in losses that increase the process costs.

Uses. Metaldehyde in pellet form is marketed as a dry fuel (Meta). Mixed with a bait, metaldehyde is used as a molluscicide.

8.3. Polyacetaldehyde

Polyacetaldehyde [*9002-91-9*] is a high-molecular-mass polymer with an acetal structure (polyoxymethylene structure):

By using cationic initiators, mainly an amorphous polymer is obtained. Temperatures below −40 °C are preferred in this case. Above −30 °C, mainly paraldehyde and metaldehyde are produced. The initiator activity also depends on the solvent used. Suitable initiators include H_3PO_4 in ether and pentane, as well as HCl, HNO_3, CF_3COOH, $AlCl_3$ in ether, and particularly BF_3 in liquid ethylene [61]. Al_2O_3 and SiO_2 also seem to be good initiators [62].

The polymer has a rubber-like consistency and is soluble in common organic solvents. It depolymerizes at room temperature, liberating acetaldehyde. It evaporates completely within a few days or weeks. Acidic compounds accelerate depolymerization, and amines (e.g., pyridine) stabilize polyacetaldehyde to a certain extent. A complete stabilization (as, for instance, in the case of polyformaldehyde) has not yet been achieved, so the polymer is still of no practical importance.

Copolymers with propionaldehyde, butyraldehyde, and allylacetaldehyde also have been produced [63]. Crystalline, isotactic polymers have been obtained at low temperatures (for example, −75 °C) by using anionic initiators [64]. Suitable initiators are alkali metal alkoxides, alkali metals, or metal alkyls in hydrocarbon solvents. The products are insoluble in common organic solvents but have an acetal structure like the amorphous polymers' [65]. Polymerization of acetaldehyde to poly(vinyl alcohol), which in contrast to polyacetaldehyde has a pure carbon backbone, has not yet been achieved [66].

9. Toxicology and Occupational Health

Acetaldehyde. At higher concentrations (up to 1000 ppm), acetaldehyde irritates the mucous membranes. The perception limit of acetaldehyde in air is in the range between 0.07 and 0.25 ppm [67, 68]. At such concentrations the fruity odor of acetaldehyde is apparent. Conjunctival irritations have been observed after a 15-min exposure to concentrations of 25 and 50 ppm [69], but transient conjunctivitis and irritation of the respiratory tract have been reported after exposure to 200 ppm acetaldehyde for 15 min [69, 70]. The penetrating odor, the low perception limit, and the irritation that acetaldehyde causes, give an effective warning so that no serious cases of acute intoxication with pure acetaldehyde have been reported. Acute acetaldehyde intoxication can also be observed following combined ingestion of disulfiram (Antabuse) and ethanol [73]. In animal experiments at high concentrations (3000 – 20 000 ppm), pulmonary edema

and a narcotic effect become evident. The clinical course is similar to alcohol intoxication. Death occurs by breath paralysis or — with retardation — by pulmonary edema.

For rats, the LC_{50} (30 min inhalation) is 20 500 ppm [71]. No studies on subchronic or chronic toxicity of acetaldehyde in humans are available. Investigations of sister chromatid exchange in cell cultures [72] and in human lymphocytes [74] and studies of single- and double-strand breaks in human lymphocytes incubated with acetaldehyde [75] have revealed mutagenic effects of acetaldehyde. Long-term exposures of Syrian golden hamsters to concentrations in the range 1650 – 2500 ppm have resulted in inflammatory hyperplastic and metaplastic alterations of the upper respiratory tract with an increase in carcinomas of the nasal mucosa and the larynx [76]. Male and female Wistar rats were exposed to aldehyde concentrations of 0 ppm, 750 ppm, 1500 ppm for 6 h daily, 5 d per week for 52 weeks. In the highest dose group, the initial aldehyde concentration of 3000 ppm was reduced to 1000 ppm in the course of the study due to toxic effects. The dose-dependent effects found were increased mortality in all dose groups and delayed growth in the middle- and highest-dose group. Adenocarcinomas were observed at all three investigated concentrations. An increased rate of squamous epithelial carcinomas was only seen at 1500 ppm or more. Histological signs of irritation were observed in the larynx region in most animals from the medium- and high-dose groups [77]. Concomitant exposure to acetaldehyde also considerably increases the number of tracheal carcinomas induced by instillation of benzo[*a*]pyrene [72]. This suggests that chronic tissue injury is a prerequisite for tumor formation by acetaldehyde. Tumors probably do not develop if doses are not sufficient to cause tissue necrosis. In male Wistar rats exposed to 150 ppm or 500 ppm for 6 h per day, 5 d per week for 4 weeks, morphological changes in the olfactory epithelium were observed in the high-dose group [78]. However, long-term toxicity data at lower exposure concentrations are not yet available.

Currently, the TLV is 25 ppm (STEL/ceiling value) [79], and the MAK is 50 ppm [80]; the latter value is preliminary. At 50 ppm acetaldehyde, no irritation or local tissue damage in the nasal mucosa is observed. Because the mechanism of action is assumed to be analogous to that of formaldehyde, acetaldehyde is regarded as a suspected carcinogen [80].

When taken up by the organism, acetaldehyde is metabolized rapidly in the liver to acetic acid. Only a small proportion is exhaled unchanged. After intravenous injection, the halflife in the blood is approximately 90 s [81].

Paraldehyde acts as a sedative with few side effects. Ingested paraldehyde partly is metabolized to carbon dioxide and water and partly is exhaled unchanged. It generates an unpleasant odor in the expired air and therefore is not much used.

Metaldehyde decomposes slowly to acetaldehyde in the presence of acids, so ingestion may cause irritation of the gastric mucosa with vomiting. As characteristic signs of a metaldehyde intoxication, especially in children, heavy convulsions (sometimes lasting several days) have been reported, with lethal outcomes, after ingestion of several grams of metaldehyde [82]. For these reasons, those molluscicides and solid fuels which contain metaldehyde must be kept away from children.

1. Introduction

Acetic acid [*64-19-7*], CH_3COOH, M_r 60.05, is found in dilute solutions in many plant and animal systems. Vinegar, an aqueous solution containing about 4 – 12 % acetic acid, is produced by the fermentation of wine and has been known for more than 5000 years.

The major producers of acetic acid, accounting for ca. 70 % of total worldwide production, are the United States, Western Europe, and Japan. World capacity exceeds 7×10^6 t/a [1]. The largest end uses are in the manufacture of vinyl acetate [*108-05-4*] and acetic anhydride [*108-24-7*]. Vinyl acetate is used in the production of latex emulsion resins for applications in paints, adhesives, paper coatings, and textile treatment. Acetic anhydride is used in the manufacture of cellulose acetate textile fibers, cigarette filter tow, and cellulose plastics.

2. Physical Properties

Acetic acid is a clear, colorless, corrosive liquid that has a pungent odor and is a dangerous vesicant. It has a pK_a of 4.77 [2]. It melts at 16.75 °C [3] and boils at 117.9 °C [4] under 101.3 kPa [5]. It has a pungent vinegarlike odor. The detectable odor is as low as 1 ppm. The acid is combustible with a low flash point of 43 °C. The explosion limits of acetic acid vary from the upper explosion limit (UEL) of 16 % at 92 °C to the lower explosion limit (LEL) of 4 % at 59 °C. The liquid is usually available as glacial acetic acid with less than 1 wt % water and over 98 % purity. Besides water, the acid contains traces of impurities such as acetaldehyde, oxidized substances, iron, and chlorides.

Occasionally, the acid may be colored due to the presence of ethyl acetoacetate [*141-97-9*].

The acetate is easily mistaken for formic acid because it reduces mercuric chloride. Traces of mercury may cause extensive corrosion by reaction with aluminum. Aluminum is a common material for containers to ship the acid [6].

Glacial acetic acid is very hydroscopic. The presence of 0.1 wt % water lowers the freezing point significantly [7]. Measuring the freezing point is a convenient way to evaluate acetic acid purity. This is shown in Table 1 [8].

Acetic acid forms azeotropes with many common solvents, such as benzene, pyridine, and dioxane. Acetic acid is miscible with water, ethanol, acetone, benzene, ether, and carbon tetrachloride. However, it is not soluble in CS_2 [2].

The physical properties of acetic acid are well documented, and their accuracy is important for commercial production. For instance, design and operation of distillation processes requires precise data. High-precision values provide a valuable asset to the chemical industry [9], [10].

The density of mixtures of acetic acid and water [11–13] is listed in Table 2. The density exhibits a maximum between 67 wt % and 87 wt %, corresponding to the monohydrate (77 wt % acetic acid). The density of pure acetic acid as a function of temperature is listed in Table 3 [14], [15].

Due to the difficulty in eliminating traces of water from acetic acid, the value for the boiling point varies from 391 to 392 K [10]. Careful studies prove that pure acetic acid boils at 391.10 K under 101.325 kPa [16]. The critical temperature and critical pressure are 594.45 K and 5785.7 kPa [3].

Precise data on vapor pressure of acetic acid are available from a regression equation (Eq. 1) [10], which covers the range from the normal boiling point to the critical point.

$$P = P_c \exp(A + B/T_r + C \ln T_r + DT_r^6) \quad (1)$$

where P is vapor pressure in kPa; T_r is reduced temperature T/T_c, T is temperature in K; T_c is 594.45 K, P_c is 5785.7 kPa, A is 10.08590, B is − 10.37932; C is − 3.87306, and D is 0.29342.

The vapor pressure of pure acetic acid is given in Table 4 [17]. The density of the vapor corresponds to approximately twice the molecular

mass because of vapor-phase hydrogen bonding [8]. Hydrogen-bonded dimers and tetramers have both been proposed. Reports indicate that in the gas phase, the acid exists mainly in an equilibrium between monomer and dimer (Eq. 2) according to vapor density data [18], [19] molecular modeling, IR analysis [20], and gas-phase electron diffraction [21].

(2)

In the gas phase, monomic and dimeric acetic acid undergo extensive hydrolysis [22], [23]. In the liquid state, acetic acid equilibrates between monomer and dihydrated dimer or cyclic dimer (Eqs. 2 and 3) [24]. As the concentration of acetic acid increases, the equilibrium shifts to the right, favoring dimeric acetic acid. As the temperature is increased, the system shifts to the left, favoring the monomer. In addition, the acid may also form open-chain trimers and higher oligomers. However, at about 95 wt %, the acid exists mainly as a cyclic dimer and is no longer associated with water.

(3)

Up to 32 wt %, mixing acetic acid with water leads to evolution of heat. At higher acid concentrations heat is absorbed [25]. The measured values of the heat of mixing are consistent with the calculated values based on the dimers and tetramers described above. The aqueous mixture of acetic acid forms a eutectic mixture at − 26 °C. This eutectic mixture prevented earlier attempts to concentrate the acid by freezing. A way to obtain pure acid is to add urea or potassium acetate to the acid. Then, glacial acetic acid can be distilled.

Other physical properties of acetic acid are listed below.

Specific heat capacity	
Gaseous acid, c_p	1.110 J g^{-1} K^{-1} at 25 °C [33]
Liquid acid, c_p	2.043 J g^{-1} K^{-1} at 19.4 °C
Crystalline acid, c_p	1.470 J g^{-1} K^{-1} at 1.5 °C
	0.783 J g^{-1} K^{-1} at −175.8 °C
Heat of fusion	195.5 J/g [29]
Heat of combustion	−874.2 kJ/mol at 20 °C [30]
Cryoscopic constant	−269.56 °C [30]
Ebullioscopic constant	270.62 °C [30]
Melting point	6.76 °C [31]
Triple-point temperature	16.93 °C [19]
Boiling point	118.0 °C at 101.3 kPa [32]

Flammability	4.0 to 16.0 vol % in air [36]
Critical data	
p_c	5.786 MPa [3]
T_c	321.45 °C [3]

3. Chemical Properties

Many useful materials are made from acetic acid; several are discussed in Chapter 9. Acetate esters are formed by reaction of olefins or alcohols with acetic acid [37]. Acetamide is prepared by the thermal decomposition of ammonium acetate. Acetic acid can be converted to acetyl chloride with phosphorous trichloride or thionyl chloride.

Acetic acid is a raw material for a number of commercial processes. It can be converted to vinyl acetate with ethylene and oxygen (→ Vinyl Esters). Acetic acid is used in the manufacture of acetic anhydride (→ Acetic Anhydride) via ketene and in the production of chloroacetic acid (→ Chloroacetic Acids) using chlorine.

4. Production

Vinegar is still made by fermentation (→ Vinegar). However, the most important synthetic

routes to acetic acid are methanol carbonylation and liquid-phase oxidation of butane, naphtha, or acetaldehyde. Methanol carbonylation has been the method of choice for the past 25 years [38–40] and will likely remain the preferred route for large-scale production.

Several new technologies for producing acetic acid are being studied. Showa Denko may produce acetic acid by the gas-phase reaction of ethylene with oxygen over a supported palladium catalyst that contains a heteropolyacid or salt [41]. Numerous patents and publications discuss the production of acetic acid directly from ethane and oxygen. Production of acetic acid and acetate salts by microorganisms has also received considerable attention.

4.1. Carbonylation of Methanol

The manufacture of acetic acid from methanol [*67-56-1*] and carbon monoxide [*630-08-0*] at high temperature and high pressure was described by BASF as early as 1913 [42].

$$CH_3OH + CO \longrightarrow CH_3COOH \quad \Delta H = -138.6\,\text{kJ}$$

In 1941 Reppe at BASF demonstrated the efficiency of group VIII metal carbonyls as catalysts for carbonylation reactions, including hydroformylation [43], [44]. This led to the development of a high-pressure, high-temperature process (700 bar, 250 °C) with a cobalt iodide catalyst. The thrust of this work was to develop an acetic acid process not dependent on petroleum-based feedstocks. The current advantage of the methanol carbonylation route to acetic acid is the favorable raw material and energy costs. The synthesis gas raw material required for this process can be obtained from a variety of sources, which range from natural gas to coal. The cobalt-based carbonylation process was commercialized in 1960 by BASF in Ludwigshafen, Federal Republic of Germany [43], [45–47]. The initial capacity of 3600 t/a was expanded to 45 000 t/a by 1981 [48]. In 1966 Borden Chemical Co. started up a 45 000 t/a acetic acid unit in Geismar, Louisiana, United States, based on the BASF technology [43], [45]. The unit was expanded to 64 000 t/a by 1981 before it was shut down in 1982 [1], [48]. This unit was brought on stream again in 1988 for one year to meet acetic acid supply shortages in the United States.

Monsanto developed a low-pressure acetic acid process in the late 1960s with a rhodium iodide promoted catalyst system that demonstrated significantly higher activity and selectivity than the cobalt-based process. Methanol can be carbonylated even at atmospheric pressure with yields of 99 % and 90 % with respect to methanol and carbon monoxide, respectively [49]. This process was proven commercially in 1970 at Texas City, Texas. The initial plant capacity of 135 000 t/a has been expanded to 270 000 t/a since 1975 [1]. Operating conditions in the reactor are much milder (3 MPa and 180 °C) than in the BASF process [50]. Soon after the Monsanto process was commercialized, the BASF process became uncompetitive, so the Monsanto process is the preferred technology for grass-roots acetic acid units. Since the start-up of the Texas City plant by Monsanto, more than ten companies have licensed and operated this technology worldwide.

In 1978 at the Clear Lake Texas Plant, Celanese Chemical Company (now Celanese, Ltd.) was the first licensee to demonstrate commercially the rhodium-catalyzed Monsanto process. Initial capacity was 27 000 t/a [51]. In the early 1980s, Celanese developed a proprietary low-reaction-water rhodium-catalyzed methanol carbonylation process by modification of the original Monsanto high-reaction-water chemistry. Modifications to the catalyst system by the addition of inorganic iodide salts improved catalyst stability and activity significantly [52]. This technology improvement enabled the Clear Lake unit to expand by more than three times the original capacity to 900 000 t/a with minor capital cost [53].

In 1986, BP Chemicals purchased from Monsanto the high-reaction-water, low-pressure, rhodium-catalyzed methanol carbonylation technology and licensing rights. The acquisition of the technology did not include the improvements developed by Celanese Chemical Company.

Monsanto in the early 1960s also discovered that iridium, like rhodium, is an effective methanol carbonylation catalyst. This catalyst system has since been developed commercially by BP in the early 1990s and is known as the Cativa process [54]. This process was uti-

lized to convert the original rhodium-catalyzed methanol carbonylation plant in Texas City to an iridium-based process. Several advantages claimed by BP for the Cativa process over the conventional rhodium-catalyzed high reaction water carbonylation process include superior catalyst stability, operation at lower reaction water, and less liquid byproducts [55].

Chemistry and Reaction Conditions. The chemistry of the cobalt- (BASF), rhodium- (Monsanto and Celanese), and iridium-catalyzed (BP) processes is similar in requiring promotion by iodide, but the different kinetics indicate different rate-determining steps. In all three processes, two important catalytic cycles are common, one that involves the metal carbonyl catalyst and one that involves the iodide promoter [56], [57].

The cobalt-catalyzed *BASF process* uses cobalt(II) iodide [*15238-00-3*] for in situ generation of $[Co_2(CO)_8]$ and hydrogen iodide [*10034-85-2*]. Compared to other methanol carbonylation processes, severe conditions are required to give commercially acceptable reaction rates. The rate of reaction depends strongly on both the partial pressure of carbon monoxide and the methanol concentration. Acetic acid yields are 90 % based on methanol and 70 % based on carbon monoxide. A proposed mechanism for the iodide-promoted reaction is summarized in Figure 1 [43], [56], [57].

The generation of the active nucleophile, $[Co(CO)_4]^-$, can be considered a water-gas shift reaction [Eq. (4a); cf. Eq. (4b)] in which $[Co_2(CO)_8]$ is the catalyst and the hydrogen formed is dissociated via the hydridocarbonyl complex.

$$[Co_2(CO)_8] + H_2O + CO \longrightarrow 2\,[Co(H)(CO)_4] + CO_2 \quad (4a)$$

Subsequently, the methyl iodide formed from hydrogen iodide and methanol undergoes nucleophilic attack by the $[Co(CO)_4]^-$ anion. Iodide facilitates this reaction because it is a better leaving group than OH^-. The CH_3I reacts with a coordinatively saturated d^{10} complex, which is the preferred electron configuration of cobalt(I). Therefore, the methyl migration to form the acyl cobalt carbonyl complex, $[CH_3C(O)Co(CO)_3]$, is less favored than the same process for the rhodium(III) species. Once formed, this acyl intermediate cannot undergo simple reductive elimination of acetyl iodide because iodide is not coordinated to cobalt. Acetyl iodide is formed from the reaction of hydrogen iodide with the acyl complex to regenerate the cobalt carbonyl anion. Rapid hydrolysis of the acetyl iodide forms acetic acid and hydrogen iodide. All of the individual steps involved in the otherwise similar mechanism can be assumed to occur at a lower rate for cobalt than for rhodium and iridium. This explains the higher temperature needed for the BASF process. In addition, higher carbon monoxide partial pressures are required to stabilize the $[Co(CO)_4]^-$ complex at the higher reactor temperatures.

Byproducts in the BASF process are CH_4, CH_3CHO, C_2H_5OH, CO_2, C_2H_5COOH, alkyl acetates, and 2-ethyl-1-butanol [58–60]. About 3.5 % of the methanol reactant leaves the system as CH_4, 4.5 % as liquid byproducts, and 2 % is lost as off-gas. Some 10 % of the CO feed is converted to CO_2 by the water gas shift reaction (Eq. 4b).

$$CO + H_2O \longrightarrow CO_2 + H_2 \quad (4b)$$

The *Monsanto process* with rhodium carbonyl catalyst [*38255-39-9*] and iodide promoter operates under milder conditions than the BASF cobalt-catalyzed process. Methanol and carbon monoxide selectivities of greater than 99 % and 90 %, respectively, are obtained [49]. The system is not as sensitive to hydrogen as the BASF process, and therefore reduction products such as methane and propionic acid are comparatively insignificant.

The chemistry of the rhodium-catalyzed methanol carbonylation reaction has been studied in detail [57]. Kinetic studies show the reaction to be zero-order in carbon monoxide and methanol, and first-order in rhodium and iodide promoter. The carbonylation rate is strongly affected by the reaction media, but the overall kinetics are unaffected by the solvent, which suggests that it does not participate in the transition state of the rate-determining step [61–64]. Methanol carbonylation in polar solvents generally provides a rate enhancement, especially with the addition of protic solvents. An acetic acid/water solvent medium is preferred [65].

Many different rhodium compounds act as effective catalyst precursors for methanol carbonylation at common reaction temperatures of

Figure 1. Reaction cycle proposed for the cobalt-catalyzed methanol carbonylation reaction (BASF process)

150 – 200 °C. The iodide promoter is normally methyl iodide, but other forms of iodide, such as hydrogen iodide or iodine, can be used without marked differences in reaction rates.

Spectroscopic investigations have shown that rhodium(III) halides can be reduced in aqueous or alcoholic media to $[Rh(CO)_2X_2]^-$ [50]. The reaction rate is independent of the rhodium precursor charged to the reaction provided adequate iodide, generally methyl iodide, and carbon monoxide are available. Under these conditions, $[Rh(CO)_2I_2]^-$ is the predominant rhodium species in the reaction solution. These observations strongly suggest the generation of $[Rh(CO)_2I_2]^-$ as the active catalyst species [50].

The catalytic cycle shown in Figure 2 is based on kinetic and spectroscopic studies [66–78]. The complex anion $[Rh(CO)_2I_2]^-$ reacts in the rate-determining step with methyl iodide by oxidative addition to form the transient methylrhodium(III) intermediate. Methyl migration gives the pentacoordinate acyl intermediate. The acyl intermediate eliminates acetyl iodide and regenerates $[Rh(CO)_2I_2]^-$. The acetyl iodide reacts with water to regenerate hydrogen iodide and produce acetic acid. Hydrogen iodide reacts with methanol to form methyl iodide. In this way both the original rhodium complex and methyl iodide promoter are regenerated.

In the 1980s *Celanese* made innovative improvements to the rhodium catalyst system of the Monsanto process with the implementation of the proprietary acetic acid optimization (AO) technology which incorporates catalyst co-promoters. Advantages of AO technology are enhanced carbonylation rates and increased carbon monoxide and methanol efficiencies at lower reaction-water concentrations [52]. These modifications represent the most significant development in rhodium-catalyzed methanol carbonylation since the development of the Monsanto process. The AO technology enabled the

Figure 2. Reaction cycle proposed for the rhodium-catalyzed methanol carbonylation reaction (Monsanto process) and with inorganic iodide co-promotion (Celanese process)

Celanese Clear Lake Plant to more than triple unit capacity from 27 000 t/a since start-up in 1978 to 90 000 t/a acetic acid in 1998 with very low capital investment [51], [53].

The increased carbonylation rates at low reaction water concentrations are achieved by catalyst promotion with iodide and acetate anions [38], [70–72]. This unique enhancement in catalyst activity is due presumably to the generation of a strongly nucleophilic five-coordinate dianionic catalyst species, namely, $[Rh(CO)_2I_2(L)]^{2-}$ ($L = I^-$ or OAc^-), which is more active than $[Rh(CO)_2I_2]^-$ toward oxidative addition of methyl iodide. This additional reaction pathway is summarized in Figure 2.

The primary byproducts and major inefficiency with respect to carbon monoxide in the rhodium-catalyzed process are carbon dioxide and hydrogen via the water gas shift reaction (Eq. 4). The water gas shift reaction is also catalyzed by $[Rh(CO)_2I_2]^-$ [50], [79–81]. The overall two-step reaction is summarized in the following:

$$[Rh(CO)_2I_2]^- + 2\,HI \longrightarrow [Rh(CO)I_4]^- + H_2 + CO$$
$$[Rh(CO)I_4]^- + 2\,CO + H_2O \longrightarrow [Rh(CO)_2I_2]^- + CO_2 + 2\,HI$$
$$\overline{CO + H_2O \longrightarrow CO_2 + H_2}$$

The proposed kinetic pathway for the water gas shift reaction is shown in Figure 2, which emphasizes the interrelation between methanol

carbonylation and water gas shift reaction as catalyzed by $[Rh(CO)_2I_2]^-$. The addition of inorganic iodide co-promoters in the Celanese process reduces significantly the proportion of $[Rh(CO)_2I_2]^-$ that catalyzes the water gas shift reaction. As a result, the conversion of carbon monoxide and methanol to acetic acid is improved over the conventional Monsanto process, and the rate of methanol carbonylation is increased [38].

Compared to the cobalt-based process, byproducts derived from methanol such as CH_4, CH_3CHO, and C_2H_5COOH are formed in very small amounts, even in the presence of significant amounts of hydrogen in the carbon monoxide feed gas [82]. This low methanol inefficiency is associated with occurrence of the rate-determining step prior to formation of a organometallic compound, the short lifetime of the methylrhodium complex, and the rapid reductive elimination of the acylrhodium complex to form acetyl iodide, which is rapidly hydrolyzed to acetic acid and hydrogen iodide.

Similar to the rhodium-based carbonylation processes, the reaction chemistry of the BP *iridium-catalyzed methanol carbonylation* is well characterized [50], [56], [57], [78], [85–88]. The iridium-catalyzed reaction proceeds through a series of similar reaction pathways to the rhodium-catalyzed system but involves a different rate-determining step. The proposed rate-determining step is methyl migration to form the iridium acyl complex. This pathway involves the elimination of iodide and the subsequent addition of carbon monoxide. The direct dependence of the reaction rate on carbon monoxide concentration and the inhibiting effect of low concentations of iodide are consistent with the rate-determining step [55], [83]. The proposed catalytic scheme for the reaction is given in Figure 3 [55]. Model studies at 25 °C demonstrate that the oxidative addition of methyl iodide to iridium is about 120 – 150 times faster than for rhodium [55], [83]. However, methyl migration on iridium is 10^5 to 10^6 times slower than for rhodium [83]. The main byproducts of the iridium-catalyzed process are also carbon dioxide and hydrogen via the water gas shift reaction (Eq. 4b). The mechanism of this reaction is similar to the rhodium-catalyzed process [57]. The production of CH_4 derived from methanol is higher for iridium than for rhodium. This observation is consistent with the greater stability of the methyliridium(III) complex associated with the hydrogenation of the iridium – carbon bond [83].

Other transition-metal complexes have been investigated as promising catalysts for methanol carbonylation, in particular, nickel complexes by Halcon and Rhône-Poulenc [57], [89], [90].

BASF Process [91] (Fig. 4).

Carbon monoxide, methanol (containing up to 60 % dimethyl ether), catalyst recycle, catalyst makeup, and methyl iodide recycle (from the wash column) are sent to the high-pressure reactor (b; stainless steel lined with Hastelloy). Part of the relatively low heat of reaction is used to preheat the feed and the rest is ultimately dissipated through the reaction vent. The reaction product is cooled and sent to the high-pressure separator (d). The off-gas goes to the wash column (o) and the liquid is expanded to a pressure of 0.5 – 1.0 MPa in the intermediate-pressure separator (e). The gas released is also sent to the wash column; the liquid from the intermediate-pressure separator is sent to the expansion chamber (f). The gas from the chamber goes to the scrubber (p). The gas from the scrubber and the wash column is discarded as off-gas. Both scrubber and wash column use the methanol feed to recover methyl iodide and other iodine-containing volatile compounds; this methanolic solution is returned to the reactor. The off-gas composition in vol % is 65 – 75 CO, 15 – 20 CO_2, 3 – 5 CH_4, and the balance CH_3OH.

The raw acid from the expansion chamber contains 45 wt % acetic acid, 35 wt % water, and 20 wt % esters, mainly methyl acetate. The acid is purified in five distillation towers. The first column (h) degasses the crude product; the off-gas is sent to the scrubber column. The catalyst is then separated as a concentrated acetic acid solution by stripping the volatile components in the catalyst separation column (i). The acid is then dried by azeotropic distillation in the drying column (k). The overhead of the drying column contains acetic and formic acids, water, and byproducts that form an azeotrope with water. This overhead is a two-phase system that is separated in the chamber (g). Part of the organic phase, composed mainly of esters, is returned to column (k), where it functions as an azeotroping agent. The remainder of the organic phase

is sent to the auxiliary column (n) where heavy ends are separated at the bottom of the column, and light esters from the overhead are recycled to the reactor. The aqueous phase and the catalyst solution are returned to the reactor. The base of the drying column is sent to a finishing column (l), in which pure acetic acid is taken overhead. The bottom stream of the finishing tower is sent to the residue column (m). The overhead of this residue column is sent back to the dehydration column. The bottom of the residue column contains about 50 wt % propionic acid, which can be recovered.

Monsanto Process [38], [83], [92] (Fig. 5).

Carbon monoxide and methanol are introduced continuously into a back-mixed liquid-phase reactor (a) at ca. 150 – 200 °C and 30 – 60 bar [38], [83], [92]. The noncondensable byproducts (CO_2, H_2, and CH_4) are vented from the reactor to control the carbon monoxide partial pressure in the reactor. The off-gas from the reactor and the purification sections of the process are combined and sent to a vent recovery system in which the light ends, including organic iodides such as methyl iodide, are scrubbed from the vent before the noncondensable gases are flared. The light ends from the vent recovery system are recycled to the reactor. The reactor solution is forwarded to the flasher (b) where the catalyst is separated as a residue stream from the crude acetic acid product and recycled to the reactor. The crude acetic acid, which contains methyl iodide, methyl acetate, and water, is taken overhead in (b) and sent to the light-ends column (c). The light components (methyl iodide, methyl acetate, and water) are recycled to the reactor as a two-phase overhead stream, while wet acetic acid is removed as a side stream from (c) and sent to the dehydration column (d). An aqueous acetic acid overhead stream from (c) is recycled to the reactor and a dry acetic acid product residue stream is forwarded to a heavy ends column (e). As a residue stream in (e), propionic acid, which is the major liquid byproduct of the process is removed with other higher boiling carboxylic acids. Product acetic acid is removed in (e) as a sidestream, and the overhead stream is recycled to the purification section of the process.

Since the Cativa process as demonstrated in the Sterling Plant at Texas City, Texas is a retrofit of the original Monsanto process, the overall general process is presumably the same, possibly with some modifications [54], [93], [94].

4.2. Direct Oxidation of Saturated Hydrocarbons

Liquid-phase oxidation (LPO) of aliphatic hydrocarbons was once practiced worldwide [95]. Due to competition from carbonylation technology, plants have reduced production by LPO significantly. The process changes depending on the availability of raw materials. Raw materials include *n*-butane and light naphtha [96]. In the United States and Canada, Celanese employs butane, while BP in the United Kingdom uses light naphtha to produce acetic acid [97]. Capacities of related production are shown in Table 5 [99].

Table 5. Butane liquid-phase oxidation processes

Company	Location	Acetic acid capacity, t/a
Celanese	Pampa, Texas	250 000 [43]
	Edmonton, Alberta, Canada	75 000 [99]
BP	Hull, England	210 000
AKZO Zout Chemie	Europoort, The Netherlands	110 000 [100]

Reaction Mechanism. Oxidation of hydrocarbons follows similar kinetics, both in the gas and liquid phases, especially in slightly polar solvents [98]. However, the mechanism of the reaction is very complicated. The reaction can be considered roughly as a radical chain reaction [99]. For example, the oxidation of butane proceeds through initiation, oxidation, propagation, and decomposition steps [96]. The initiation and propagation probably involve radicals abstracting hydrogen from a secondary carbon atom of butane. Subsequent reaction with oxygen yields hydroperoxides. These intermediates decomposes to produce acetic acid. Catalysts, agitation, and high temperature accelerate the decomposition.

Catalysts are not essential for LPO [100]. However, metal catalysts may influence the distribution of products, induction period, and operating temperature [101], [102].

In a simple mechanism, the first step of oxidation is the abstraction of a secondary hydrogen

Figure 5. Production of acetic acid (Monsanto process)
a) Reactor; b) Flasher; c) Light-ends column; d) Dehydration column; e) Heavy-ends column

atom (Eq. 5) to give alkyl radicals. The oxygen in the solvent rapidly converts these radicals to *sec*-butylperoxy radicals [103] (Eq. 6). In other interpretations, oxygen is believed to directly react with one or two alkane molecules to form radicals (Eqs. 7 and 8) [104], [105], [106]. Initiation, especially with catalysts, affects the induction period significantly [107].

$$RH + In^{\bullet} \longrightarrow R^{\bullet} + HIN \tag{5}$$

$$R^{\bullet} + O_2 \longrightarrow ROO^{\bullet} \tag{6}$$

$$RH + O_2 \longrightarrow R^{\bullet} + HOO^{\bullet} \tag{7}$$

$$2\,RH + O_2 \longrightarrow 2\,R^{\bullet} + HOOH \tag{8}$$

$$ROO^{\bullet} + RH \longrightarrow ROOH + R^{\bullet} \tag{9}$$

$$ROOH \longrightarrow RO^{\bullet} + HO^{\bullet} \tag{10}$$

$$ROO^{\bullet} + ROO^{\bullet} \longrightarrow ROOOOR \tag{11}$$

$$ROO^{\bullet} + M^{n+} \longrightarrow ROO^{-} + H^{+} + M^{(n+1)+} \longrightarrow ROOH \tag{12}$$

$$ROOH + M^{n+} \longrightarrow RO^{\bullet} + OH^{-} + M^{(n+1)+} \tag{13}$$

$$ROOOOR \longrightarrow RO^{\bullet} + O_2 + RO^{\bullet} \tag{14}$$

(15)

In general, peroxy radicals do not abstract hydrogen efficiently from other molecules, so the reaction medium contains an abundance of these radicals. Each radical abstracts hydrogen from an alkane to form a hydroperoxide and an alkyl radical (Eq. 9). Alkyl radicals propagate the chain (Eq. 6).

The hydroperoxide decomposes to give an alkoxy radical by thermolysis. The radical undergoes a bimolecular reaction to terminate the formation of radicals (Eq. 11). In the steady state, the termination of radicals is balanced by their production. This mechanism is too simple to explain the reaction in detail. In real systems, thermolysis may not be the only course of decomposition [108].

Alternatively, hydroperoxides may come from the complexation of metal catalysts with peroxy radicals (Eq. 12). Hydroperoxide radicals generate new radicals (Eqs. 10, 13). Therefore, the catalyst is important in maintaining a constant flux of radicals. However, in certain cases, catalysts may actually inhibit the decomposition [109].

Manganese and cobalt are common catalysts for LPO. These metals accelerate the decomposition of hydroperoxide. There is evidence that manganese may enhance the oxidation of ketone intermediates through a mechanism involving enols [110].

The peroxy radicals terminate by forming tetroxides (Eq. 11), which decompose to yield alkoxy radicals and oxygen (Eq. 14).

If the tetroxide has an α-hydrogen atom, the decomposition may follow a Russel mechanism [111]. The products are oxygen, a ketone, and an alcohol (Eq. 15). However, the mechanism is controversial. Recent reports both support [112] and challenge the mechanism [113].

Besides hydrogen abstraction, alkoxy radicals can participate in β-scission (Eq. 16). Products vary depending on the structure of the radicals. Primary, secondary, and tertiary alkoxy radicals yield alcohols, aldehydes, and ketones, respectively.

The mechanism of butane oxidation is complex. However, with detailed understanding of product distribution and rates, a mathematical model was developed [103].

About 25 % of the carbon of consumed butane appears as ethanol in the initial step as the first isolable non-peroxidic intermediate. The reaction probably involves decomposition of *sec*-butoxy radicals to form acetaldehyde and an ethyl radical (Eqs. 16, 17). Another source of acetaldehyde is the oxidation of ethanol. Acetaldehyde then reacts rapidly to produce acetic acid. Therefore, acetaldehyde is a major intermediate in butane LPO.

(16)

$$CH_3CH_2^{\bullet} + O_2 \longrightarrow CH_3CH_2OO^{\bullet}$$

$$2\,CH_3CH_2OO^{\bullet} \longrightarrow 2\,CH_3CH_2O^{\bullet} + O_2$$

$$CH_3CH_2O^{\bullet} + RH \longrightarrow CH_3CH_2OH + R^{\bullet} \qquad (17)$$

Besides acetaldehyde, 2-butanone or methyl ethyl ketone is another major byproduct. The ketone is the result of the termination of *sec*-butylperoxy radical by the Russel mechanism (Eq. 15).

Other impurities include propionic acid and butyric acid. *sec*-Butoxy radicals undergo β-scission to yield propionaldehyde. Oxidation of the aldehyde gives propionic acid. Butyric acid is derived from *n*-butyl radicals.

Higher paraffins are oxidized by similar mechanisms to that of butane. However, the products include shorter chain methyl ketones and difunctional intermediates. These are the results of intramolecular hydrogen abstraction. European countries usually produce acetic acid from naphtha since naphtha is cheap and available. However, the naphtha-based processes yield large amounts of impurities that increase the cost of purification.

Industrial Operation [6, 114–116] (Fig. 6). Air or oxygen-enriched air can be used as the oxidant. Multivalent metal ions, such as Mn, Co, Ni, and Cr, are used as catalysts. Some processes, however, are noncatalytic. Reaction conditions are 150 – 200 °C for a range of reaction pressures that include 5.6 MPa. The reaction pressure for naphtha oxidation is lower. The reaction solvent consists of acetic acid, varying amounts of intermediates, water, and dissolved hydrocarbons. Control of the water concentration below some maximum level appears to be critical.

The reaction section (a – d) of a liquid-phase oxidation unit consists of a sparged tubular reactor or column (a) and one or more phase separation vessels (b – d) for separating the gas and two liquid phases from the reactor. The hydrocarbon vapor exiting the reactor (a) can be recovered for recycling. Normally the reactor vapor is expanded through a turbine (b) to recover duty to compress air for use in the reactor. The consequent reduction in temperature condenses the hydrocarbon. The top organic layer from the phase separator (d) is rich in hydrocarbons and is recycled to the reactor. The bottom, aqueous layer, is distilled to recover the hydrocarbon for recycle.

The residual, hydrocarbon-free product consists of volatile, neutral oxygenated derivatives (aldehydes, ketones, esters, and alcohols),

water, volatile monocarboxylic acids (formic, acetic, propionic, and butyric from butane), and nonvolatile materials (difunctional acids, γ-butyrolactone, condensation products, catalyst residues, etc).

The volatile neutral substances can be recovered as mixtures or individually. They are used for derivatives, sold, or recycled to the reactor. Most of these components generate acetic acid on further oxidation.

The separation of water and formic acid from acetic acid involves several distillations (f). Water removal is the most difficult and costly step of the purification process. It is accomplished by azeotropic distillation with entrainment agents, such as ethers, or by extractive methods.

Formic acid is separated from the resulting anhydrous acetic acid usually by fractionation with an azeotroping agent. The remaining higher boiling acids are separated from acetic acid as a residue stream by fractionation.

In some cases, hydrocarbons such as heptane and isooctane can be added to the reactor to improve separation. These chemicals form a high-boiling azeotrope with formic acid.

In the case of naphtha oxidation, diacids such as succinic acids are isolated for sale [117]. The nonvolatile residue can be burned to recover energy.

4.3. Acetaldehyde Process

Oxidation of acetaldehyde represents a major process for making acetic acid [6], [8] (Eq. 18).

$$CH_3CHO + 1/2\,O_2 \longrightarrow CH_3COOH \qquad (18)$$

Although oxidation reactions are rather complex, a simplified view is presented here. The oxidation of acetaldehyde to acetic acid proceeds through a free-radical chain which produces peracetic acid as an intermediate.

Iniation:

(19)

Propagation:

(20)

(21)

Peracetic acid reacts with acetaldehyde to generate acetaldehyde monoperacetate [*7416-48-0*]. The acetaldehyde monoperacetate decomposes efficiently to acetic acid by a hydride shift in a Baeyer – Villiger reaction. The methyl migration leads to the byproduct methyl formate [118]:

The alkyl migration becomes more pronounced with higher aldehydes, particularly aldehydes having a branch at the α-position.

Chain termination occurs primarily through bimolecular reactions of acetylperoxy radicals via an intermediate tetroxide (Eq. 22). [119].

(22)

Figure 6. Oxidation of *n*-butane in the liquid phase (Chemische Werke Hüls process)
a) Reactor; b) Air cooler; c) Collector; d) Separation vessel; e) Pressure column; f) Distillation column

(23)

(24)

(25)

Equations (23)–(25) are the source of most of the carbon dioxide, methanol, formaldehyde, and formic acid byproducts. Uncatalyzed oxidation is efficient so long as the conversion of acetaldehyde is low and there is a significant concentration of aldehyde in the solvent. This keeps the steady state concentration of acetylperoxy radicals low and favors the Baeyer–Villiger reaction over the reactions (23)–(25). Special precautions must be taken in the uncatalyzed reaction to prevent the concentration of acetaldehyde monoperacetate from reaching explosive levels [6].

At low oxygen concentrations another free-radical decomposition reaction becomes important (Eq. 26).

(26)

The rate of decarbonylation increases with increasing temperature. Decarbonylation becomes significant when insufficient oxygen is present to scavenge the acetyl radicals.

Catalysts can play several important roles in aldehyde oxidations [120]. Catalysts decompose peroxides and so minimize the explosion hazard (Eq. 27). In addition, manganese also reduces acetylperoxy radicals [121] directly to peroxy anions [122]:

(27)

(28)

Reaction with Mn^{2+} assists in suppressing the concentration of acetylperoxy radicals. The Mn^{3+} formed can generate the acyl radical for

the propagation step (Eq. 28), but does not contribute to inefficiency-generating reactions.

Manganese also greatly increases the rate of reaction of peracetic acid and acetaldehyde to produce acetic acid [123]. The reaction in the presence of manganese is first-order with respect to peracid, aldehyde, and manganese. In addition, the decomposition replenishes the supply of radicals. This is important since the oxidation requires a constant flux of radicals. Manganese ions increase both the rate and efficiency of oxidation.

Copper can interact synergistically with a manganese catalyst [124]. Manganese has some negative aspects associated with the fact that it greatly increases the reaction rate [125]. The increased reaction rate leads to oxygen starvation and an increasing steady state concentration of radicals. Both contribute to byproduct formation by decarbonylation and decarboxylation. However, Cu^{2+} can oxidize acetyl radicals very rapidly (Eq. 29) [126].

(29)

The acetylium ion can react as shown in Equation (30).

(30)

Peroxide or Mn^{3+} can reoxidize the Cu^{+}. Copper diverts a fraction of the reaction through a nonradical pathway and consequently provides a termination step that does not result in inefficiency.

Another effective catalyst is cobalt. At low concentration, this catalyst shortens the induction period [126]. The cobalt catalyst is regenerated by decomposing peracetic acid. In kinetic studies [127], CH_3CO_3 was the main free radical in the liquid phase. Other catalysts, for example phosphomolybdic acids [128], also catalyze acetaldehyde oxidation.

Additional byproducts from acetaldehyde oxidation include ethylidene diacetate, crotonic acid, and succinic acid.

Industrial Operation. A typical acetaldehyde oxidation unit is depicted in Figure 7. The reactor (a) is sparged with air or oxygen-enriched air. Temperatures are typically 60 – 80 °C with pressures of 0.3 – 1.0 MPa. The reaction mixture is circulated rapidly through an external heat exchanger to remove the heat of reaction. The vent gas is cooled and then scrubbed with recirculated crude product (which goes to the reactor) and finally with water (which goes to the aldehyde recovery column). The reactor product is fed to the aldehyde recovery column (b), from which the aldehyde is recycled, and then to a low-boilers column (c) in which methyl acetate is removed. The next column is the acetic acid finishing column (d), where water is removed overhead by azeotropic distillation and finished product comes off as a vapor sidestream. Yields are generally in excess of 90 % and purity is greater than 99 %.

4.4. Other Processes

Acetic Acid from Ethylene. Efforts to convert ethylene directly to acetic acid without going through an acetaldehyde isolation step have been of interest. Although the price of ethylene generally makes this process unattractive, some developments are noteworthy. Effective oxidation of ethylene to acetic acid has been demonstrated with metal oxides such as vanadium pentoxide. Seone et al. [129] demonstrated that the presence of palladium enhances etylene oxidation to acetic acid as temperatures as low as 230 °C. Showa Denko combined palladium with heteropolyacids and patented a catalyst for producing acetic acid from ethylene and oxygen. The catalyst contains palladium, an heteropolyacid, such as silicotungstic acid, and potassium tellurite or potassium selenite. The process is operated at 150 °C and 0.7 MPa. Although water is not consumed in the reaction, the presence of water enhances the selectivity to acetic acid and is recommended.

Figure 7. Oxidation of acetaldehyde to acetic acid
a) Reactor; b) Acetaldehyde column; c) Methyl acetate column; d) Finishing column; e) Column for recovering entrainer; f) Off-gas scrubber column

Acetic Acid from Ethane. Several groups have investigated catalysts for the conversion of ethane to acetic acid (Eq. 31).

$$C_2H_6 + 3/2\,O_2 \longrightarrow CH_3CO_2H + H_2O \qquad (31)$$

Union Carbide [130] developed the Ethoxene process for the production of ethylene from ethane and oxygen. The earliest catalysts consisted of molybdenum, vanadium, and niobium oxides and were very selective for ethylene at temperatures below 300 °C. Unfortunately, ethane conversions were low (about 10 %) due to inhibition by the product. Further development [131] focused on the coproduction of ethylene and acetic acid with a catalyst comprised of molybdenum, vanadium, niobium, calcium, and antimony. The addition of water enhances acetic acid formation. A later patent [132] discloses that the addition of water and an ethylene hydration catalyst improves selectivity to acetic acid.

Rhône-Poulenc [133], [134] has patented a process to make acetic acid from ethane with a vanadium oxide or vanadyl pyrophosphate supported on titanium dioxide. Tessier et al. [135] found that acetic acid production was favored over ethylene and carbon oxides at temperatures below 300 °C. Roy et al. [136] demonstrated that the addition of molybdenum enhanced acetic acid selectivity. Desorption of acetic acid from the catalyst surface was speculated to be the rate-determining step of the reaction.

BP Chemicals [137], [138] claims that the addition of rhenium to mixed metal oxide catalysts enhances selectivity to acetic acid from the oxidation of ethane and/or ethylene. Again, water is used to enhance selectivity to acetic acid. Standard Oil [139] claims good selectivity to acetic acid with a vanadyl pyrophosphate catalyst containing a transition metal. Hoechst [140] claims a catalyst containing molybdenum and palladium as effective for the production of acetic acid from ethane. An acetic acid selectivity of 84 % was attained at 250 °C and 7 bar with a 14-s residence time.

Although ethane is an inexpensive raw material and high selectivities to acetic acid have been achieved, it is unlikely that ethane oxidation will compete with methanol carbonylation in the near future. The oxygen concentration must be limited for safety reasons and therefore ethane conversion is limited per pass in the reactor. Although staged addition of oxygen is possible, product inhibition remains a problem and limits ethane conversion. Since the addition of water is needed to improve selectivity to acetic acid, water must be removed from the acetic acid, usually by extractive distillation.

Acetic Acid from Microorganisms Since about 10 000 B.C., aqueous solutions of acetic acid have been prepared from spoiled wine [141], [142]. Ethanol and sugar were the primary feedstocks for microorganism production of acetic acid, although biomass has been proposed [143]. The concentration of acetic acid in solution is limited by the ability of bacteria to thrive in low-pH solutions. Consequently,

researchers have focused on improving acetic acid productivity and lowering the pH of the bacterial culture. Mutant strains of *Clostridium thermoaceticum* [144] have been developed to produce acetic acid in solutions below pH 5. Improvement of acetic acid productivity of an *Acetobacter aceti* strain was achieved by amplification of the aldehyde dehydrogenase gene with a multicopy vector [145]. Bacterial production is gaining interest since it is a environmentally friendly process. Nevertheless, cost-effective acetic acid concentration and purification remain a challenge.

4.5. Concentration and Purification

In most commercial processes acetic acid is purified from an aqueous acetic acid solution by straight distillation methods that are economically viable provided the acetic acid is in high concentrations when initially isolated from the reaction system of the process. Other acetic acid purification techniques can be used, in particular, for dilute acetic acid such as byproduct streams of important industrial processes, e.g., cellulose acetate production (→ Cellulose Esters). Azeotropic distillation, solvent extraction, and extractive distillation can recover acetic acid from these aqueous streams. Direct distillation requires a significant number of plates and a high reflux ratio in the columns. In extractive distillation, the vapor streams of acetic acid and water are scrubbed with a high-boiling solvent that preferentially dissolves one of the components.

Azeotropic Distillation. In azeotropic distillation, a compound that decreases the boiling point of water is used. If the azeotropic agent is immiscible with water, it can be separated easily from water and recycled. Esters, ethers, benzene, and chlorinated hydrocarbons have been proposed as azeotropic agents [146].

Solvent Extraction. Acetic acid is removed from aqueous solutions (0.5 – 5 wt % acetic acid) by solvent extraction. The aqueous solution is contacted with an organic solvent, often containing an organic base, and then acetic acid is stripped from the base in a distillation process and separated from the cosolvent, usually an alkane, by phase separation. Consequently, it is important for the organic solvent to have a high affinity for acetic acid relative to water. Primary amines are generally not suitable extraction additives due to their water solubility. Secondary amines have high extraction coefficients [147] but can form amides during the acid recovery process. Tertiary amines such as trioctylamine [148] have extraction coefficients which are strongly dependent on amine concentration and the cosolvent used. Eyal and Canari [149] discuss how anion exchange, ion-pair formation, hydrogen-bond formation, and solvation all play important roles in amine-based extraction of acetic acid. In addition to amines, dibutyl phosphonate [150] and trioctyl phosphine oxide [151] have high extraction coefficients relative to alcohols, ethers, or esters.

The selection of a water-removal method depends on economics. Extraction is generally preferred at low concentrations of acetic acid.

4.6. Construction Materials [152], [153]

Little is known about construction materials for equipment in acetic acid processes. The information on materials is usually considered a trade secret. Liquid streams containing acetic acid corrode metals. The corrosion increases with increasing concentrations of acetic acid, halides, and formic acid. High temperatures (> 200 °C) also increase the corrosion rate. AISI 316 stainless steel [*12597-68-1*] is used for processes without reducing agents and halides. In the presence of reducing agents, AISI 321 stainless steel is necessary. Hastelloy B or C or other materials are required if halides are present. Aluminum [*7429-90-5*] and AISI 304 stainless steel are used in storage tanks, pumps, and piping at room temperature and high acid concentrations. AISI 316 stainless steel contains 16 – 18 wt % Cr, 10 – 14 wt % Ni and 2 – 3 wt % Mo. AISI 321 stainless steel has 17 – 19 wt % Cr, 9 – 12 wt % Ni and > 0.4 wt % Ti. AISI 304 stainless steel is comprised of 18 – 20 wt % Cr and 8 – 10.5 wt % Ni.

5. Wastewater and Off-Gas Problems [154]

Waste streams from acetic acid process usually contain residual acetic and formic acids.

These acids must be recycled, diluted, or treated chemically and then degraded biologically. European countries require neutralization or biological degradation of these waste streams [6], [8].

Acetic acid is corrosive and can damage human skin and internal organs. Acetic acid should be handled with care to avoid breathing vapors. If a spill occurs, neutralize soil and wash with soda ash or lime. The Clean Water Act (USA) and Superfund (USA) dictate that a reportable quality (RQ) of 2270 kg (5000 lb) [155].

In Germany [156], no more than 3 kg/h may be emitted in vent gases, with a maximum of 150 mg/m^3. The vent gas is scrubbed or chilled to eliminate the acids.

Under the same German regulations, the maximum emissions for methyl acetate, ethyl acetate, butyl acetate, and phenyl acetate are 300 mg/m^3. The off-gas is limited to 6 kg/h [8]. The recommended methods of removal of the acetic acid are thermal condensation, washing with nonvolatile organic solvent, physical absorption or burning.

In the United States, the United States Clean Air Act governs the amount of emissions. Each state also sets individual emission limits. The limits range from 0.25 mg/m^3 to 0.37 mg/m^3 (North Dakota), to 0.4 mg/m^3 (Virginia) to 0.5 mg/m^3 (Connecticut and South Dakota) to 0.595 mg/m^3 (North Carolina) [154].

6. Quality Specifications

There is essentially one commercial grade of acetic acid sold in the United States. Elsewhere, three or more grades are available differing as to specifications for heavy metals, chloride, sulfate, arenic, and iron [157]. Also, depending on specific end uses, additional product criteria must be considered. For example, in the manufacture of vinyl acetate, halides are important since they are a catalyst poison in vinyl acetate processes. One of the most critical specifications for all end uses of acetic acid is "permanganate time." The test for "permanganate time" is a semi-quantitative wet method for the measurement of oxidizable impurities. One manufacturer's sales specification is given Table 6 [76].

Table 6. Sales specifications for glacial acetic acid [76]

Sales specifications	Limits
Acetic acid, wt %	min. 99.85
Distillation range (including 118.1), °C	max. 1.0
Freezing point, °C	min. 16.35
Color, Pt – Co units	max. 10
Water content, wt %	max. 0.15
Reducing substances, as formic acid, wt %	max. 0.05
Aldehydes, as acetaldehyde, wt %	max. 0.05
Iron, ppm	max. 1
Heavy metals, as Pb, ppm	max. 0.05
Chlorides, ppm	max. 1
Sulfates, ppm	max. 1
Sulfurous acid, ppm	max. 1
Permanganate time	min. 2 h

7. Analysis

Gas chromatography is the usual technique for determining the acetic acid content of a volatile mixture. Packed columns can be used, but capillary columns are preferred. Carbowax 20M, terephthalic acid terminated [*41479-14-5*], is the preferred substrate.

8. Storage, Transportation, and Customs Regulations [8], [152], [159]

DOT regulations regard glacial acetic acid (99.7 %) as a hazard. The acid belongs to UN/DOT Hazard Class 8 and Shipping Group II [160]. Acetic acid should be stored in a cool, dry place away from contact with oxidizing materials. Containers should be kept closed and labeled as "Corrosive". Precautionary labels such as "Flammable" are recommended. Even when emptied, the containers may still retain acid residue. Wash the container with water. The emptied container should still have a warning label.

The acid can be stored and transported in containers lined with stainless steel, glass, or polyethylene. Another material for containers is aluminum. Aluminum forms a protective coating of aluminum oxide or aluminum acetate when exposed to acetic acid. The coating prevents further corrosion. Caution is warranted to prevent water and mercury contamination. Water and small amounts of mercury accelerate the

corrosion. Maintaining a high acid concentration and not using a mercury thermometer help to prevent catastrophic corrosion.

The limits for shipping concentrated acetic acid in passenger aircraft or railcar is 1 L, and 30 L in cargo aircraft. Acetic acid has a low melting point of 16 °C. Transporting the acid in cold weather requires the vessels to be heated. Storage containers, tank trucks, and pipes for concentrated acid should be equipped with heated coils. Storage vents also need to be heat traced to prevent the acid from crystallizing.

German Legal Requirement for Foodstuffs. Commercial vinegar exceeding 11 wt % acetic acid may be sold in closed containers. The material of the containers should be resistant to acetic acid. The container must be clearly marked with a label warning as "Handle with Care.", "Do Not Swallow Undiluted." Solutions containing more than 25 wt % acetic acid are not available to the public. Commercial dealers are allowed to handle the acid.

German Customs Requirements (Vinegar Law) [5]. The Vinegar Law, Paragraph 1, dictates that the transfer of synthetic vinegar in retail markets is taxable. The tax is known as the Vinegar Tax. Both imported and local products are subjected to the tax. With changing of vinegar price, the tax is adjusted.

Tax exempt status is granted for acetic acid used in commercial purposes. Another case for tax exempt status also deals with commercial uses where the acid is consumable by humans.

9. Uses

Acetic acid has a broad spectrum of applications. An outline of these is given in Figure 8 [1], [48]. Greater than 65 % of the acetic acid produced worldwide goes into polymers derived from vinyl acetate (→ Vinyl Esters), or cellulose (→ Cellulose Esters). Most of the poly(vinyl acetate) is used in paints and coatings or for making poly(vinyl alcohol) and plastics. Cellulose acetate is used to produce acetate fibers. Acetic acid and acetate esters are used extensively as solvents.

10. Derivatives

This section contains information about acetic acid derivatives that are not discussed in detail elsewhere in this encyclopedia (→ Acetic Anhydride, → Cellulose Esters, → Chloroacetic Acids, → Esters, Organic, → Vinyl Esters).

10.1. Salts

10.1.1. Aluminum Acetate

Three aluminum acetates are known, two basic and one neutral: $Al(OH)_2CO_2CH_3$ [*24261-30-1*], $Al(OH)(CO_2CH_3)_2$ [*142-03-0*], and $Al(CO_2CH_3)_3$ [*139-12-8*].

Properties. $Al(CO_2CH_3)_3$, M_r 204.1, is a white, water-soluble powder that decomposes at about 130 °C to give acetic anhydride along with basic aluminum acetates [161].

Production. Neutral aluminum acetate is made from aluminum metal and glacial acetic acid that contains 0.1 – 1 % acetic anhydride, which scavenges any water present [162]. The anhydrous triacetate cannot be made from aqueous solutions. The basic acetates can be prepared from $Al(OH)_3$ and aqueous acetic acid solutions [163].

Uses. Aluminum acetate is used as a dye mordant in the dyeing of fabrics.

10.1.2. Ammonium Acetate

Properties. Ammonium acetate [*631-61-8*]. $CH_3CO_2NH_4$, M_r 77.08, *mp* 114 °C, forms colorless, hygroscopic needles. The solubilities of this salt in 100 g of water or methyl alcohol are, respectively, 148 g (4 °C) and 7.9 g (15 °C).

Production. Ammonium acetate is manufactured by neutralizing acetic acid with ammonium carbonate or by passing ammonia gas into glacial acetic acid [114]. Acidic ammonium acetate, $CH_3CO_2NH_4 \cdot CH_3CO_2H$ [*25007-86-7*], is manufactured by dissolving the neutral salt in acetic acid.

Uses. Ammonium acetate is used in the manufacture of acetamide and as a diuretic and diaphoretic in medical applications. The wool industry also uses this salt as a dye mordant.

Figure 8. Uses of acetic acid

10.1.3. Alkali Metal Salts

Properties. All of the alkali metals (Li, Na, K, Rb, Cs) form acetates. The aqueous solubilities of these salts increase with increasing atomic mass of the alkali metal [164]. The potassium salt [*127-08-2*]. M_r 98.14, *mp* 292°C, and sodium salt [*127-09-3*], M_r 82.04, *mp* 324°C, are the most common. The former crystallizes from water as white columns. The latter can be purified by crystallization from acetic acid. Several acetic acid solvates of the alkali metal salts are known [163].

Production. Potassium and sodium acetates normally are manufactured from glacial acetic acid and the corresponding hydroxides. The salts also can be prepared from acetic acid on treatment with the metal, the metal carbonate, or the metal hydride [163].

Uses. Potassium acetate is used to purify penicillin. It is also used as a diuretic and as a catalyst to make polyurethane. The sodium salt is used frequently in water as a mild alkali.

10.2. Esters (→ Esters, Organic) [166–169]

Properties. Physical properties of acetate esters are listed in Table 7 [168].

Production. The reaction of an alcohol and an organic acid produces an ester in the presence of an acid catalyst [166]. The reaction, esterification, is the most common process for manufacturing acetate esters (Eq. 32).

$$ROH + CH_3COOH \rightleftharpoons CH_3COOR + H_2O \tag{32}$$

Other industrial processes include the reaction of acetic anhydride with alcohols and the Tishchenko reaction. Other methods for synthesizing acetate esters are the addition of acetic acid to olefins, carbonylation of acetic acid or anhydride, and reductive methods involving carboxylic acids or anhydride.

Commercial processes for esterification are usually continuous and are performed in the liquid phase. The reaction requires strong acids such as sulfuric acid or organic sulfonic acids. Another type of catalyst is ion-exchange resins. In contrast, gas-phase technology is available with sulfonated polymer [170] or supported phosphoric acid as catalyst [171].

Esterification involves an equilibrium between reactants and product (Eq. 33). Adding excess reactants or removal of water drive the equilibrium to favor the formation of ester. Azeotroping agents eliminate water and force the reaction to completion. Common agents are cyclohexane, benzene, and toluene.

$$K_{eq} = \frac{[CH_3COOR]\,[H_2O]}{[CH_3COOH]\,[ROH]} \tag{33}$$

Esterification with acetic anhydride offers an alternative route for making acetates. Due to its high reactivity, acetic anhydride readily forms esters with alcohols. The reaction is irreversible. The esterification goes to completion without eliminating products or water.

Additions of acetic acid to olefins present an alternative way to make acetates, especially for branched esters. Synthesis of these hindered esters by esterification is not efficient. The equilibrium does not favor the desirable products. Rhône-Poulenc uses this method to prepare isopropyl acetate from acetic acid and propylene [172]. Catalysts can be strong protic or Lewis acids, like sulfuric acid or $BF_3 \cdot OEt_2$ [173]. Ethyl acetate can also be produced directly from acetaldehyde.

Adding hydrogen and carbon monoxide to acetic acid or acetic anhydride can produce acetates. Alternatively, hydrogenation of acetic acid yields ethanol and ethyl acetate. Many studies relate to supported heterogeneous catalysts with molybdenum and group VIII metals (Pd, Rh, or Ru). Additionally, homogeneous catalysis with ruthenium can result in high selectivity [172].

Commercial processes also include the reaction of aldehdyes to make esters. The Tischenko reaction uses alkoxide catalysts. Typical catalysts are aluminum alkoxide, boric acid and magnesium or calcium aluminum alkoxides [173].

Uses. Applications of acetates depend on their physical properties such as boiling point and evaporation rate. Therefore, uses of acetates cover many products such as coatings, solvents for plastics, lacquers, resins, and gums.

Table 7. Physical properties of acetate esters

Ester	CAS no.	M_r	n_D^{20}	d_{20}^{20}	*bp*, °C	*fp*, °C	Flash pt., °C
Methyl acetate	[*141-78-6*]	74.1	1.36	0.93	57.0	−98.1	−10
Ethyl acetate	[*108-05-4*]	88.1	1.37	0.902	77.1	−83.6	− 4
Propyl acetate	[*109-60-4*]	102.13	1.38	0.887	101.6	−92.5	13
Isopropyl acetate	[*108-21-4*]	102.13	1.38	0.872	90.1	−73.4	2
Butyl acetate	[*123-86-4*]	116.16	1.39	0.882	126.0	−73.5	22
Isobutyl acetate	[*110-19-0*]	116.16	1.39	0.871	117.2	−98.6	18
sec-Butyl acetate	[*105-46-4*]	116.16	1.39	0.876	112.0		31
tert-Butyl acetate	[*540-88-5*]	116.16	1.39	0.867	97.0		
n-Pentyl acetate	[*628-63-7*]	130.18	1.40	0.876	149.2	−70.8	
2-Ethylhexyl acetate	[*103-09-3*]	172.26	1.42	0.873	199.3	−93.0	71

10.2.1. Methyl Acetate

Properties. Methyl acetate is colorless and has a pleasant odor. Methyl acetate forms azeotropes with water (3.5 wt % H_2O, *bp* 56.5 °C) and methanol (19 wt % MeOH, *bp* 54.0 °C). Other properties are listed in Table 7.

Production. Most commercially available methyl acetate is a byproduct in the manufacture of acetic acid. Another method is the esterification of methanol and acetic acid with sulfuric acid as catalyst. The product ester is removed as the methanol/methyl acetate azeotrope.

Uses. Methyl acetate has the lowest boiling point (55.8 – 58.2 °C) of all organic acetates. It evaporates about five times faster than butyl acetate [166]. Therefore, methyl acetate finds uses where rapid evaporation is necessary. It is employed as a process solvent for preparing cellulose nitrates. Transesterification to make esters uses methyl acetate as a reagent. In addition, the production of acetic anhydride requires the acetate.

10.2.2. Ethyl Acetate

Properties. Ethyl acetate has a pleasant odor. It forms azeotropes with water (8.2 wt % H_2O, *bp* 70.4 °C), ethanol (30.8 wt % EtOH, *bp* 71.8 °C), and methanol (44 wt % MeOH, bp 60.2 °C). With water and ethanol, the ester forms a ternary azeotrope (7.8 wt % H_2O, 9.0 wt % EtOH, *bp* 70.3 °C). Other properties are listed in Table 7.

Production. Ethyl acetate is made from ethanol [*64-17-5*] and acetic acid in batch or continuous processes. A major step in the continuous process is the removal of the ester. The distillation process separates the ester by taking advantage of the alcohol – ester – water azeotrope. After decanting and purification, the final yield of the ester can reach as high as 95 %.

Another means of making ethyl acetate is theTischenko reaction. Two moles of acetaldehyde can undergo bimolecular reaction to yield ethyl acetate with a metal alkoxide catalyst at low temperature (Eq. 34). A popular catalyst is aluminum alkoxide.

(34)

Uses. Ethyl acetate is a common solvent for coatings, adhesives, ink, cosmetics, and film base. Specialty chemicals and pharmaceutical industries use ethyl acetate as a solvent for synthesis. Coffee is occasionally decaffeinated with ethyl acetate in an extraction process.

10.2.3. Butyl Acetate

Properties. All four of the esters, *n*-butyl [*123-86-4*], *sec*-butyl [*105-46-4*], isobutyl [*110-19-0*], and *tert*-butyl acetate [*540-88-5*], are colorless liquids with pleasant odors. Azeotropic data for the butyl acetates are given in Tables 8 and 9 [5]. Other properties are listed in Table 7.

Table 8. Binary azeotropes with the butyl acetates

Component A	Component B	*bp*, °C	wt % B
n-Butyl acetate	Water	90.2	26.7
sec-Butyl acetate	Water	86.6	19.4
Isobutyl acetate	Water	87.4	–
n-Butyl acetate	*n*-Butanol	117.2	47
sec-Butyl acetate	*sec*-Butanol	99.6	86.3

Table 9. Ternary azeotropes with the butyl acetates

Component A	Component B	Component C	*bp*, °C	wt % B	wt % C
n-Butyl acetate	Water	*n*-Butanol	89.4	37.3	37.3
sec-Butyl acetate	Water	2-Butanol	86.0	23.0	45.0
Isobutyl acetate	Water	Isobutyl alcohol	86.8	30.4	23.1

Production. Esterification of butanol and acetic acid produces butyl acetate. The catalyst is sulfuric acid. The removal of water by azeotropic separation forces the reaction to completion. The acid catalyst is neutralized and the ester purified by distillation [8].

Uses. Butyl acetate is used primarily in coatings. It is a good solvent with low volatility. The lacquer and enamel industries employ butyl acetate as a solvent for making acylic polymers, vinyl resins, and nitrocellulose. Other industries utilizing the acetate as solvent include printing, photographic, adhesives, extraction and pharmaceutical.

10.2.4. 2-Ethylhexyl Acetate

2-Ethylhexyl acetate is prepared by esterification of 2-ethyl-1-hexanol with acetic acid with the aid of an acid catalyst. Distillation with a low-boiling azeotropic solvent removes water from the reaction. The ester is used in lacquers, in silk-screen inks, and in paints as a coalescing agent. Properties are listed in Table 7.

10.2.5. Other Esters

Properties of some other esters are given in Table 7. Most esters are colorless liquids with a mild fruity smell. The esters are used as solvents for making cellulose and elastomers [178].

10.3. Acetyl Chloride

Properties. Acetyl chloride [*75-36-5*] M_r 78.5, n_D^{20} 1.3871, d_4^{20} 1.1051, *bp* 51.8°C, *mp* −112.86 °C is a colorless, corrosive liquid. Acetyl chloride reacts with moist air to produce hydrogen chloride and acetic acid.

Production. The normal industrial method involves reaction of acetic anhydride [*108-24-7*] with anhydrous hydrogen chloride [*7647-01-0*] [179], [180]. On the laboratory scale, it can be produced from acetic acid and reagents such as thionyl chloride [*7719-09-7*], phosphorus trichloride [*7719-12-2*], or phosphorus pentachloride [*10026-13-8*] [181].

Acetyl chloride is normally consumed at the site of generation since transportation and storage are difficult. Glass, enamel, porcelain, clay, and polytetrafluoroethylene are suitable materials for handling acetyl chloride.

Uses. Acetyl chloride is an efficient acetylating agent for alcohols and amines to produce esters and amides. It is important in the synthesis of dyes and pharmaceuticals. Acetyl chloride is used in the Friedel – Craft acylation of benzene to yield acetophenone.

10.4. Amides

10.4.1. Acetamide

Properties. Acetamide [*60-35-5*], CH_3CONH_2, M_r 59.07, *mp* 81.5 °C, *bp* 222°C, d^{20} 1.161, forms deliquescent hexagonal crystals that are odorless when pure. Acetamide is soluble in water and low molecular mass alcohols.

Production. Acetamide can be produced by several methods. Ammonia reacts vigorously with acetyl halides or acetic anhydride to produce acetamide. Alkyl acetates also react with ammonia to yield acetamide. Dehydration of ammonium acetate is the standard procedure for preparation of acetamide. Finally, acetonitrile is hydrolyzed to yield acetamide in the presence of an acid or base catalyst. Metal catalysts [183], [184] and biocatalysts [185] are claimed to catalyze the hydrolysis of acetonitrile. This method of acetamide production is popular because acetonitrile is a byproduct of acrylonitrile production.

Uses. Acetamide is used as a solvent and as a plasticizer.

10.4.2. *N,N*-Dimethylacetamide

Properties. *N,N*-Dimethylacetamide, [*127-19-5*], $CH_3CON(CH_3)_2$, M_r 87.1, *mp* −20 °C, *bp* 165.5 °C, d^{20} 0.943, is a colorless liquid which is soluble in a wide variety of solvents.

Production. *N,N*-Dimethylacetamide is prepared by reaction of dimethylamine with acetic acid, acetic anhydride, or acetate esters. Heating dimethylamine acetate with [186], [187] or without [188] a catalyst affords *N,N*-dimethylacetamide. Reaction of dimethylamine with acetate esters requires a catalyst; sodium methoxide is typically used.

Uses. *N,N*-dimethylacetamide is an excellent solvent and often acts as a catalyst in halogenation, cyclization, and alkylation reactions. *N,N*-Dimethylacetamide is used in the spinning of polyacrylonitrile and as a solvent in the processing of other polymers. *N,N*-dimethylacetamide lithium chelate complexes intercalate cationic sites in layered silicates [189].

10.5. Phenylacetic Acid

Properties. Phenylacetic acid [*103-82-2*], $C_6H_5CH_2CO_2H$, M_r 136.14, *bp* 265.5 °C, *mp* 78 °C, $d^{79.8}$ 1.0809, forms white leaflets on vacuum distillation. It dissolves in hot water but is only slightly soluble in cold water.

Production. Hydrolysis of benzyl nitrile or carbonylation [190] of benzyl halides or alcohols produces phenylacetic acid [191].

Uses. Penylacetic acid is a starting material in the synthesis of synthetic perfumes and cosmetics [192]. It is used in the synthesis of penicillin G to stimulate benzylpenicillinase in *E. Coli*. Penicillin G, after extraction from the culture, is converted to 6-aminopenicillanic acid and phenylacetic acid.

11. Economic Aspects [1]

World acetic acid production between 1998 and 2006 is forecast to grow by an average of 3 – 4 % per annum, while world acetic acid capacity will grow by an average of 4 % per annum. In 1996 total world acetic acid capacity was ca. 7.1×10^6 t/a and total world production was ca. 5.5×10^6 t/a.

In 1996, North America was the region with the greatest acetic acid production at ca. 36 % of the world total. Western Europe was second with ca. 24 % followed by Japan at 15 % and Eastern Asia with 14 %. By 2006 the share of acetic acid production in North America, West Europe, and Japan is expected to drop to ca. 32 %, 17 %, and 11 %, respectively, while East Asian production will increase to 18 %. Consumption and production of acetic acid in Asia are forecast to grow strongly from 1998 to 2006.

The largest end uses of acetic acid are for the manufacture of vinyl acetate, acetic anhydride, acetate esters, monochloroacetic acid, and as a solvent in the production of dimethyl terephthalate and terephthalic acid. Figure 8 provides a detailed summary of acetic acid end uses. Vinyl acetate is by far the most significant end use for acetic acid. About 43 % of world production of acetic acid in 1996 was used in the manufacture of vinyl acetate. About 12 – 15 % of world acetic acid production is used for each of the remaining major end uses of acetic acid.

There is little doubt that the technology of the future is methanol carbonylation. In 1972, low-pressure methanol carbonylation in the United States accounted for only 10 % of the total acetic acid capacity, whereas in 1982 the share had increased to 40 %. By 1993, 46 % of the acetic acid was produced by methanol carbonylation. Over 90 % of all new acetic acid is manufactured by low-pressure methanol carbonylation technology.

BP Chemicals purchased the technology and license rights to the Monsanto methanol carbonylation process in 1986 and has continued to license in joint ventures this high-reaction-water process. Technology improvements have been made in the rhodium-catalyzed carbonylation process since this process was first implemented commercially [52]. Celanese in the early 1980s departed from the Monsanto high-water technology to develop a proprietary low-reaction-water process. BP also has developed a low-reaction-water technology based on iridium called Cativa

that has several advantages over the rhodium-catalyzed high-reaction-water process [55] originally developed by Monsanto. These developments, as well as others, will most likely ensure that in the future the low-pressure methanol carbonylation processes will remain the most economical routes to manufacture acetic acid.

Acetic acid from low-pressure methanol carbonylation is gradually replacing the more expensive acetic acid produced by the oxidation of acetaldehyde, butane, and naphtha and by high-pressure methanol carbonylation. The oxidation routes to acetic acid in most cases are not competitive with low-pressure methanol carbonylation. Acetaldehyde oxidation units are only economically viable provided an acetic acid producer has a captive source of acetaldehyde. Similarly, *n*-butane or naphtha oxidation processes are not competitive with low-pressure methanol carbonylation unless byproduct credits are considered. As a result, many high-cost acetic acid units have ceased operation, such as the acetaldehyde oxidation processes of Celanese in Clear Lake and Bay City Texas, and a similar process of Eastman Chemical in Kingsport, Texas. Additionally, the butane oxidation plant operated by Union Carbide at Brownsville, Texas, and the high-pressure methanol carbonylation plant of Borden in Geismar, Louisiana, have ceased operation.

12. Toxicology and Occupational Health

Acetic acid has a pK_a of 4.5. The acid is not as strong as mineral acids or formic acid. However, its corrosiveness justifies caution in handling.

Table 10 lists exposure limits for acetic acid and derivatives [194].

When humans ingest acetates, the esters are hydrolyzed readily to the corresponding alcohols and carboxylic acids. A study using radioactive labeling shows that the liver and brain cholesterol incorporate acetic acid [195]. No cumulative toxicity has been reported.

Dilute acid with 5 % acetic acid such as vinegar can cause irritation to human mucous membranes. Vinegar contains 3 – 6 % acid. Persons of older than two years can take as much as 2.1 g daily. However, the dilute acid damages skin more severely than other mineral acids because it is miscible with lipids.

Acetic acid irritates the eyes, nose, and throat above 10 ppm. Repeated exposure to 26 ppm for ten days causes adverse effects. Over 100 ppm, the acid may even damage organs as described above.

Concentrated acid can damage skin severely. Avoid exposure to glacial acetic acid or inhaling vapor. In case of contact, wash the exposed area with plenty of water. Therefore, handling of the acid requires caution.

Oral ingestion of the acid causes pain in the digestive tract and in the mouth. It may lead to vomiting, and respiratory and circulatory distress. If the person is conscious, wash the mouth with water and consult physicians.

Acetic acid has a low flash point of 39 °C [196]. It is readily combustible with an autoignition point of 516 °C. Fortunately, the acid lowers its flammability significantly when mixed with water. Beyond 56 %, the flash point is no longer a danger [197].

Organic acetates do not cause severe damage unless high exposure occurs. The TLVs vary from 5 to 400 ppm [198]. The LD_{50} for small mammals range from 0.4 to 16 g/kg. The toxicity of the esters decreases as the molecular mass increases from C_1 to C_4. The LD_{50} of isoamyl acetate (7.42 g/kg) is twice that of methyl acetate (3.7 g/kg). However, ingestion or absorbtion of methyl acetate poses a hazard since the ester is converted to methanol.

Acetates irritate the mucous membrane slightly. When ingested or absorbed, esters are readily hydrolyzed to the corresponding alcohols and carboxylic acids. Some volatile esters act as asphyxiants and narcotics.

Ethyl acetate has an LD_{50} of 4.97 g/kg in the rabbit. The toxicity of acetates is usually in the range of 100 – 250 ppm. Ethyl acetate has the highest PEL of 500 ppm. Humans can tolerate up to 400 ppm before nose and throat irritation.

n-Butyl acetate differs from its isomers. When tested with rats, *n*-butyl acetate has an oral LD_{50} of 14 mg/kg. For humans, irritation in the throat starts at an exposure of 200 ppm [194]. Severe eye and nose irritation occurs at 300 ppm. *sec*-Butyl acetate poses less hazard than its normal isomer, with less odor and less irritation. The lethal dose for *sec*-butyl acetate in rabbits is 4.8 mg/kg.

Table 10. Exposure limits to acetic acid and its derivatives [93], [94]

Substance	TLV				MAK	
	TWA		STEL			
	ppm	mg/m^3	ppm	mg/m^3	mL/m^3	mg/m^3
Acetic acid	10	25	15	37	10	25
n-Butyl acetate	150	713	200	950	200	950
sec-Butyl acetate	200	950			200	950
Dimethylacetamide (skin)	10	36			10	35
Ethyl acetate	400	1400			400	1400
Methyl acetate	200	606	250	757	200	610

Acetyl chloride is harmful if swallowed, inhaled, or absorbed through the skin. Target areas include the peripheral nervous system, sense organs, CNS (behavior), lungs, thorax and respiratory system. Acetyl chloride reacts with moist air to produce hydrogen chloride and acetic acid.

Amides are more hazardous than esters. Acetamide causes skin and eye irritation. It is also irritating to the mucous membranes and the upper respiratory tract. It is considered a carcinogen and has been shown to alter DNA in mouse and rat embryos. Methylacetamide has teratogenic and neoplastic potential. *N,N*-Dimethylacetamide causes hallucinogenic effects similar to those of LSD at doses of 400 mg/kg [199]. *N,N*-dimethylacetamide overexposure has led to reproductive disorders in laboratory animals. Target organs include the liver, kidney, and CNS. For humans, damage to the liver occurs at the exposure level of 20 – 25 ppm. The recommended TLV is 10 ppm without skin exposure.

Phenylacetic acid is irritating to the eyes, skin, mucous membranes, and upper respiratory system.

1. Acetic Anhydride

Acetic anhydride [*108-24-7*], $(CH_3CO)_2O$, was first prepared by C. GERHARDT in 1852 by the reaction of benzoyl chloride with molten potassium acetate. Today it is one of the most important organic intermediates and is used widely in both research and industry.

1.1. Physical Properties

Acetic anhydride, $C_4H_6O_3$, M_r 102.09, *mp* −73.1 °C, *bp* 139.5 °C (at 101.3 kPa), is a colorless liquid with a pungent odor and is strongly lachrymatory. The most important physical data are given below.

Critical pressure	4680 kPa
Critical temperature	296 °C
Vapor pressure	

t, °C	20	40	60	80	100	120
p, kPa	0.4	1.7	5.2	13.3	28.7	53.3

Density	d_{20}^{20} 1.0838; d_{20}^{-195} 1.3290; d_{20}^{-79} 1.277; d_4^{15} (1.0870) up to d_4^{50} (1.0443), see [1]
Refractive index n_D^{20}	1.39038
$n_{322\,nm}^{16}$	1.4174
$n_{667.8\,nm}^{16}$	1.3897, see [2]

Acetic anhydride is miscible with polar solvents and dissolves in cold alcohol with slow decomposition. The solubility of acetic anhydride in water at 20 °C is 2.6 wt %, with slow decomposition; the solubility of water in acetic anhydride at 15 °C is 10.7 wt %, with gradual decomposition. An overview of the solubilities of several anhydrous organic and inorganic compounds is given in [7].

Data on the kinetics of hydrolysis in water or aqueous mixtures of acids, bases, or organic solvents, with or without additives and at different temperatures, are given in [8]. Rate constants for the solvolysis in alcohols or alcoholic mixtures of organic solvents, with or without additives, are also given.

Melting points of acetic acid – acetic anhydride mixtures are as follows:

% acetic acid	100	80	60	40	20	10
mp, °C	16.7	5.4	−5.8	−19.8	−44.8	−68.1

The vapor-liquid equilibrium curve for mixtures of acetic acid and acetic anhydride is shown in Figure 1; this is of great importance in industry. Further vapor – liquid equilibria, for example, with water, benzene, diketene, propionic acid, pyrimidine, and water + acetic acid are given in [8].

Safety data:

Flash point	52.5 – 53 °C (closed cup, ASTM 56 – 70, DIN 51755)
Ignition temperature	315 °C
Explosive limits in air (20 °C, 101.3 kPa)	

1.2. Chemical Properties

Acetic anhydride undergoes a large variety of chemical reactions and is by far the most researched aliphatic carboxylic acid anhydride. In about half of the several thousand relevant publications and patents over the last 25 years, acetic anhydride was used for the acetylation of OH or NH groups (at least for the primary step). Many special reactions of acetic anhydride are summarized in [9].

Figure 1. Equilibrium curve: acetic acid – acetic anhydride

1.2.1. Acetylation

O-Acetylation. Acetic anhydride is particularly suitable for the esterification of alcohols, a reaction that is difficult or impossible with acetic acid. Acetic acid is set free in the course of the reaction. Bases and strong acids as well as salts, such as sodium acetate, are suitable as catalysts. Examples of the reaction with hydroxyl groups are the formation of acetyl cellulose, acetylsalicylic acid (Aspirin), and glycerol triacetate (→ Cellulose Esters, → Salicylic Acid, → Glycerol).

Carboxylic Acid reactions are described in Chap. 2 (→ Carboxylic Acids, Aliphatic; → Carboxylic Acids, Aromatic).

Hydrogen peroxide reacts with acetic anhydride to give peracetic acid [*79-21-0*] or diacetyl peroxide [*110-22-5*], depending on the molar ratio of the reactants:

$$(CH_3CO)_2O + 2\,H_2O_2 \rightleftharpoons 2\,CH_3CO_3H$$

$$(CH_3CO)_2O + H_2O_2 \rightleftharpoons CH_3COOH + CH_3CO_3H$$

$$(CH_3CO)_2O + CH_3CO_3H \rightleftharpoons CH_3CO\text{-}OO\text{-}COCH_3 + CH_3COOH$$

N-Acetylation. Acetylation of compounds containing NH groups yields acetamides following the general equation:

$$RR'NH + (CH_3CO)_2O \rightarrow RR'N\text{-}COCH_3 + CH_3COOH$$

where R, R′ = H or alkyl.

Amines. Aliphatic amines usually react without heating. Aniline gives acetanilide (→ Aniline), the acetyl group of which prevents oxidation during subsequent nitration. N-Acetylation generally occurs faster than the acetylation of OH groups. Therefore partial acetylation of compounds with several functional groups is possible. Examples of such reactions are the production of N-acetylamino acids, such as *N*-acetylmethionine-*S*-oxide (**1**) [10] and of N-acetylanthranilic acids (**2**) [11].

1

2

Amides and Carbamides. Aliphatic and aromatic carboxylic acid amides as well as carbamides with a free NH group can be acetylated with acetic anhydride. Strong acids, such as sulfuric acid, are most often used as catalysts. The breadth of application of this reaction can be seen from the following products: *N,N,N′,N′*-tetraacetylethylenediamine [*10543-57-4*] [12],

$(CH_3CO)_2NCH_2CH_2N(COCH_3)_2$

and 2,4,6,8-tetraacetylazabicyclo [3.3.1] nonane-3,7-dione [13]:

C-Acetylation. Compounds with reactive CH bonds can be acetylated with acetic anhydride, with the aid of a catalyst if necessary. Examples are the production of ethyl α-cyanoacetoacetate [*634-55-9*], $CH_3COCH(CN)COOC_2H_5$, (catalyst: K_2CO_3) [14] and the Friedel-Crafts reaction of acetic anhydride with aromatic hydrocarbons, for example, with benzene to form acetophenone (→ Ketones), as well as with unsaturated hydrocarbons. An interesting example of the latter group is the acetylation of 2,3-dimethylbutadiene tricarbonyl iron in the presence of aluminum chloride [15] to give the following complex:

The reaction of ketones with acetic anhydride using boron trifluoride as a catalyst gives β-diketones [16]. Triacetylmethane [*815-68-9*] can be synthesized directly from isopropenyl acetate, acetic anhydride, and aluminum chloride catalyst [17]. In the same way, unsaturated methyl ketones can be produced by acetylation of olefins with acetic anhydride in the presence of zinc chloride as catalyst [18]:

Acetylation of Mineral Acids. The reaction of nitric acid with acetic anhydride gives acetyl nitrate [*591-09-3*], which is used often as a nitrating agent in organic chemistry. For example, it is used in the production of 2-nitrocyclohexanone [*4883-67-4*], a precursor of ε-caprolactam [19]. Acetyl nitrate can be synthesized also from dinitrogen pentoxide and acetic anhydride.

Other strong acids that form mixed anhydrides include sulfuric acid [20], sulfonic acids [21], and hydrochloric acid. The reaction of acetic anhydride with phosphorous acid leads to 1-hydroxyethane-1,1-diphosphonic acid [22]:

Acetylation of Oxides. Acetic anhydride reacts with antimony trioxide to give antimony triacetate, $Sb(OCOCH_3)_3$ [*5692-86-4*] [23]. The corresponding reaction with chromium trioxide

leads to chromyl acetate solutions [24], which often are used to oxidize olefins and hydrocarbons and which may occasionally explode [25].

Acetylation of Salts. Various salts react with carboxylic acid anhydrides in the same way as the corresponding free acids [26]:

$$\mathrm{Li\text{-}C \equiv CR + (CH_3CO)_2O} \rightarrow \mathrm{CH_3CO\text{-}C \equiv CR + CH_3COOLi}$$

With barium peroxide, diacetyl peroxide [*110-22-5*] is obtained [27]:

$$\mathrm{BaO_2 + (CH_3CO)_2O \longrightarrow (CH_3CO)_2O_2 + BaO}$$

A general method of producing vinyl ketones is the reaction of vinyl magnesium bromides and acetic anhydride [28]:

$$\mathrm{2\ CHR{=}CHMgBr + 2\,(CH_3CO)_2O \xrightarrow{THF} 2\,CHR{=}CHCOCH_3 + MgBr_2 + (CH_3COO)_2Mg}$$

Production of Acetoxy Silanes. Acetic anhydride reacts with silanes according to the equation:

$$\mathrm{-\overset{|}{\underset{|}{Si}}{-}X + (CH_3CO)_2O \longrightarrow -\overset{|}{\underset{|}{Si}}{-}OCOCH_3 + CH_3COX}$$

where X = H, Cl [29]; OR [30]; NR_2 [31].

Addition to Heterocyclic Compounds with Ring Cleavage. These reactions differ only formally from those described above. Examples are the production of ethylene glycol diacetate [*111-55-7*] from ethylene oxide in the presence of strongly acidic [32] or basic [33] catalysts and the production of oxymethylene diacetates from trioxane [34].

Oxidative Addition to Carbon-Carbon Double Bonds. Oxidative addition leads to the corresponding diacetates, as for example in the addition of ethylene, which leads to ethylene glycol diacetate [35]:

$$\mathrm{CH_2{=}CH_2 + (CH_3CO)_2O \xrightarrow[1/2\,O_2]{Re_2O_7} CH_3CO{-}OCH_2CH_2O{-}COCH_3}$$

1,4-Diacetoxy-2-butene [*18621-75-5*] can be obtained from butadiene in a similar manner [36].

Production of Mixed Diacyl Peroxides. Diacyl peroxides can be made by the reaction of oxygen with mixtures of aliphatic aldehydes and acetic anhydride in the presence of sodium acetate [37]:

$$\mathrm{2\,RCHO + (CH_3CO)_2O \xrightarrow{2O_2} 2\,RCO{-}OO{-}COCH_3 + H_2O}$$

Reaction with N-Oxides. Reactions with N-oxides lead to a variety of products, depending on the type of N-oxide. From pyridine-*N*-oxide, 2-acetyloxypyridine is obtained [38]. However, 4-picoline-*N*-oxide yields a mixture of 4-acetyloxymethylenepyridine and 3-acetyloxy-4-methyl- pyridine [39]. In the Polonovski reaction of N-oxides, formaldehyde and unsaturated aldehydes are formed as well as the acid amides [40], as in the following example:

$$\mathrm{(CH_3)_2\overset{\overset{O}{\uparrow}}{N}(CH_2)_n{-}CH{=}CH_2 \xrightarrow{(CH_3CO)_2O} CH_3\overset{\overset{COCH_3}{|}}{N}(CH_2)_n{-}CH{=}CH_2 + CH_2O + CH_3(CH_2)_n{-}CH{=}CH{-}CHO}$$

Reaction with S-Oxides. The reduction of sulfoxides to sulfides with acetic anhydride is known as the Pummerer reaction [41]:

$$\mathrm{CH_3SOR + (CH_3CO)_2O \rightarrow CH_3COOCH_2SR + CH_3COOH}$$

An interesting use of this reaction is the oxidation of primary and secondary alcohols, even when sterically hindered, by mixtures of dimethylsulfoxide (or tetramethylene sulfoxide) and acetic anhydride, to give the corresponding carbonyl compounds [42]:

Production of Acylals and Vinyl Acetates. Aldehydes react with acetic anhydride in the presence of acid catalysts to form acylals:

$$RCHO + (CH_3CO)_2O \longrightarrow RCH(OCOCH_3)_2$$

If R has an α-hydrogen atom available, the corresponding vinyl acetate forms by elimination of acetic acid. The temperature required for the reaction can be lowered by adding catalysts [43–45].

A similar process is particularly suitable for the synthesis of 2,2-dichlorovinyl acetate [*36597-97-4*]. Here, in the absence of an α-proton, cleavage of the acetic acid moiety is facilitated by the presence of zinc [46]:

$$Cl_3CCHO + (CH_3CO)_2O \rightarrow Cl_3CCH(OCOCH_3)_2 \xrightarrow{Zn} Cl_2C{=}CH{-}OCOCH_3 + ClZnOCOCH_3$$

Boron Trifluoride. Acetic anhydride and substituted acetic anhydrides can be converted into acetyl ketones via a boron trifluoride complex that decomposes in warm water [16], [47].

1.2.2. Dehydration

Acetic anhydride is used as a dehydrating agent, for example, in the explosives industry. The most important example of dehydration is in the production of hexogen (1,3,5-trinitrohexahydro-1,3,5-triazine) [*121-82-4*] [16]:

In the production of the nitroester of 1,2,4,5-tetrahydroxy-3,6-dinitrocyclohexane [48], the water-binding property of the anhydride is used again:

Alkyl cyanides can be made by dehydrating aldoximes with acetic anhydride [49].

$$RCH{=}NOH + (CH_3CO)_2O \longrightarrow RCN + 2\,CH_3COOH$$

Acetic anhydride serves as a dehydrating agent in a large number of cyclization reactions.

1.2.3. Reactions of the α-Protons

The Perkin reaction is used for the production of α,β-unsaturated acids from aromatic aldehydes, such as benzaldehyde, in the presence of potassium acetate or sodium acetate. This reaction is also suitable for synthesizing cinnamalacetic acid [50]:

$$C_6H_5CH{=}CHCHO + (CH_3CO)_2O \xrightarrow[140\,^\circ C]{CH_3COOK} CH_3COOH + C_6H_5CH{=}CHCH{=}CHCOOH$$

Other examples of this type of reaction are the oxidative carboxymethylation with acetic anhydride and oxidizing agents [51] and the conversion of long-chain alkenes to the corresponding carboxylic acid derivatives [52].

1.2.4. Reactions of a Single Carbonyl Group

In some cases, it is possible to make just one of the carbonyl groups of acetic anhydride participate in a reaction. Examples are the reaction with hydrogen cyanide, in the presence of a base, to form (**3**) [53] and in the presence of Grignard reagent (RMgBr) to form (**4**) [54]:

3 **4**

1.2.5. Production of Silver Ketenide

Silver acetate and acetic anhydride react at room temperature in pyridine to form a pyridine complex of silver ketenide. When an excess of anhydride is used, silver ketenide is obtained after

fractional distillation of pyridine and acetic acid [55], [56]:

1.3. Production

History. The oldest process for making acetic anhydride is based on the conversion of sodium acetate with an excess of an inorganic chloride, such as thionyl chloride, sulfuryl chloride, or phosphoryl chloride. In this process, half of the sodium acetate is converted to acetyl chloride, which then reacts with the remaining sodium acetate to form acetic anhydride:

$$CH_3COONa + X\text{-}Cl \longrightarrow CH_3COCl + XONa$$

$$CH_3COONa + CH_3COCl \longrightarrow (CH_3CO)_2O + NaCl$$

where $X = SOCl, SO_2Cl, POCl_2$.

A further development, the conversion of acetic acid with phosgene in the presence of aluminum chloride, has the advantage that it allows continuous operation:

$$2\,CH_3COOH + COCl_2 \longrightarrow (CH_3CO)_2O + 2\,HCl + CO_2$$

Two other methods also were used in the past: the cleavage of ethylidene diacetate to form acetaldehyde and acetic anhydride in the presence of acid catalysts, such as zinc chloride, and the reaction of vinyl acetate with acetic acid on palladium(II) contacts to form acetaldehyde and acetic anhydride [16]. Not one of these processes is now of any industrial importance.

Today, acetic anhydride is made mostly by either the ketene process or the oxidation of acetaldehyde. Production by another process, the carbonylation of methyl acetate (Halcon process), was begun in 1983. In Western Europe, 77 % of acetic anhydride is made by the ketene process and 23 % by the oxidation of acetaldehyde. Since production by the Halcon process began at the Tennessee-Eastman plant, 25 % of acetic anhydride in the United States has been made by this process and 75 % by the ketene process.

1.3.1. Ketene Process

The ketene process for the production of acetic anhydride proceeds in two steps: the thermal cleavage of acetic acid to form ketene and the reaction of ketene with acetic acid:

$$CH_3COOH \rightarrow CH_2{=}C{=}O + H_2O \qquad \Delta H = 147\ \text{kJ/mol}$$

$$CH_2{=}C{=}O + CH_3COOH \rightarrow (CH_3CO)_2O \qquad \Delta H = -63\ \text{kJ/mol}$$

1.3.1.1. Production of Ketene

Thermal Cleavage of Acetic Acid. Hot acetic acid vapor is broken into ketene and water at 700 – 750 °C in the presence of traces of phosphoric acid catalyst. The pressure in the reactor is generally reduced so that the ketene can be isolated before it reacts with acetic acid or with water. The cleavage takes place in a multicoil reactor with coils made of highly heat-resistant steel alloys. The alloy Sicromal, containing 25 % Cr, 20 % Ni, and 2 % Si, is particularly suitable. Triethyl phosphate is employed as the catalyst [57].

Figure 2 shows how the vacuum process operates. Acetic acid is fed continuously into the evaporator (a). The acetic acid vapor leaving the evaporator passes over the catalyst evaporator (b), which is supplied continuously with catalyst, and thence into the ketene oven (c). The acetic acid is heated (d) and then cleaved (e). As soon as the cracked gases have left the oven, ammonia is added to prevent the ketene from reacting with the water or with the remaining acetic acid. For the same reason, and also to remove condensable gases, the hot gas is cooled in combined water and brine condensers (f), (g). A 40 – 48 % aqueous solution of acetic acid condenses at about 0 °C and is separated (h) from the cleavage gas (0 – 10 °C). About 4 – 8 % of this acetic acid results from the reaction of the condensed acetic anhydride with water. This process has been developed by the Consortium für Elektrochemische Industrie, the research institute of Wacker-Chemie.

Figure 2. Cleavage of acetic acid by the vacuum process
a) Acetic acid evaporator; b) Catalyst evaporator; c) Ketene oven; d) Convection zone; e) Cleavage zone; f) Water cooler; g) Brine cooler; h) Separator; i) Receiver

The construction of the ketene oven depends strongly on the power required. In small ovens (ca. 50 t/month), separate preheating and cleaving ovens are preferred. The acetic acid is cleaved in a spiral tube which is usually electrically heated. Ovens of medium size (up to ca. 700 t/month), however, are often constructed as single-chamber ovens, generally heated with gas or oil. For capacities of 700 t/month, product loss is to be expected. This is because of the unsatisfactory pressure conditions in the cleavage zone. Ovens with much greater capacities work satisfactorily with three- and four-chamber systems and partial gas flows [58]. It is also possible to operate several ovens with acetic acid supplied from a central evaporator.

Thermal Cleavage of Acetone. This variation of the ketene process (cleavage of acetone into ketene and methane [59]) has no economic significance for the manufacture of acetic anhydride today.

1.3.1.2. Reaction of Ketene with Acetic Acid

Two processes are available for the reaction of ketene with acetic acid. The classical *scrubber process* is being replaced gradually by the *Wacker process* with liquid-ring pumping [60]. A further process [61], in which the reaction occurs at higher temperatures, has not yet gained industrial importance.

Scrubber Process (see Fig. 3). The ketene emerging from the separator (Fig. 2) is absorbed by glacial acetic acid circulating in scrubbers (a) and (b), which are filled with Raschig rings [62]. The circulation is maintained by centrifugal pumps and the heat of reaction removed by coolers (f). Most of the ketene is absorbed in scrubber (a), the rest in scrubber (b). The liquid mixture leaving scrubber (a) contains 85 – 90 % raw anhydride and is collected in (g), cooled and used in scrubber (c) to wash the off-gas from (b). The off-gas from (c) is finally washed with brine-cooled, dilute acetic acid in scrubber (d) in order to remove acid.

Figure 3. Scrubber process
a), b), c), d) Scrubbers; e) Centrifugal pumps; f) Coolers; g) Collecting vessel; h) Vacuum pump; i) Ring – balance manometer

Wacker Process (Liquid-ring pump process) (see Fig. 4). The ketene emerging from the separator (Fig. 2) is pumped through a Nash Hytor liquid-ring pump (a) at about 13 – 20 kPa. It reacts in the pump, at about 45 – 55°C, with acetic acid. At the same time, the liquid-ring pump provides the vacuum required for the acetic acid cleavage. Reaction and compression heat are removed by passing the raw anhydride through a cooler (c). This serves simultaneously as separator for the off-gas from the cleavage reactor. The off-gas is burnt in the ketene oven after passing the measuring point (d) or is led to a flare system. The raw anhydride (90 %) is collected continuously. Part of the anhydride is returned to the reaction pump, where it is used as the reaction medium. Advantages of this process stem from the impressive simplicity of the apparatus and operation, which lead to high reliability and the possibility of producing raw anhydride of higher purity [60].

Figure 4. Wacker process (Liquid – ring pump process)
a) Liquid – ring pump; b) Pump; c) Cooler; d) Measuring point

1.3.1.3. Pure Anhydride Distillation

The raw anhydride can be distilled either continuously or discontinuously. In discontinuous distillation, three fractions are obtained:

Forerun (1 %) is about 40 % acetic acid; the rest consists of volatile liquids, particularly methyl acetate and acetone.
Middle run (about 10 %). Depending on the quality of the column, it contains 30 – 60 % acetic anhydride; the rest is acetic acid.
Pure Anhydride. Using discontinuous distillation at normal pressures, the purity of the anhydride cannot exceed 99 % (the remainder is acetic acid) because, at the still temperature required, a certain amount of decomposition occurs. These difficulties can be overcome by operating under reduced pressure.

For continuous distillation, two or three columns are used, depending on the required number of fractions (forerun and middle run are separated). The middle run portion is returned to the reactor as reagent acid. The residue of the distillation contains small amounts of tarry products and is worked up continuously in a Sambay evaporator.

A newer continuous and energy-saving vacuum process works with two evaporators and only one column [63].

The *Wacker process,* described above (see Fig. 4), is also particularly suitable as a workup process. Waste acids, such as those from cellulose acetylation, can be processed after concentration without difficulty. No auxiliary materials are necessary, only energy in the form of gas, oil, or electric current. The process has been adopted by many firms. For the production of 100 kg acetic anhydride, about 122 kg acetic acid is required, taking account of the reconcentrated dilute acetic acid. The yield is over 96 % at about 75 % cleavage.

1.3.1.4. Environmental Problems

No significant environmental problems arise with the processes described above. The off-gas occurring in the production of ketene consists of ca. 45 % carbon monoxide, 15 – 20 % carbon dioxide, ca. 15 % ethylene, ca. 10 % methane, ca. 7 % propylene, and less than 1 % acetic acid and ethane. The remainder is air. The off-gas can be burnt in the ketene oven saving energy (ca. 10 %), or led to a flare system. There are no wastewater problems.

1.3.2. Oxidation of Acetaldehyde

Acetic anhydride can be obtained directly by liquid-phase oxidaton of acetaldehyde. The peracetic acid formed from oxygen and acetaldehyde reacts under suitable conditions with a second molecule of acetaldehyde to form acetic anhydride and water [64]:

$$CH_3CHO + O_2 \rightarrow CH_3CO_3H \xrightarrow{CH_3CHO} (CH_3CO)_2O + H_2O$$

Rapid removal of the reaction water and the use of suitable catalysts are essential in this process. Mixtures of acetic acid and acetic anhydride are always obtained; their ratio can be varied within wide limits by changing the reaction conditions. Generally, the highest possible anhydride yield is sought.

Because of the rapid hydrolysis of acetic anhydride above 60 °C, the process is operated preferably between 40 °C and 60 °C [65]. Suitable catalysts are combinations of metal salts [66]. Particularly important are mixtures of manganese acetate and copper acetate [67], of cobalt acetate and nickel acetate, and of cobalt and copper salts of higher fatty acids [68]. Manganese acetate should hinder the formation of explosive amounts of peracetic acid during the oxidation of acetaldehyde. For increasing the rate of oxidation, the use of pure oxygen at a pressure of several hundred kilopascals instead of air has been proposed [69].

The strongly exothermic reaction requires efficient cooling. For this purpose, the addition of low-boiling solvents has been found to be of assistance. Methyl and ethyl acetates are favored because they form azeotropic mixtures with water (but not with acetic acid or acetic anhydride) and hence allow a rapid, continuous separation of the water formed in the reaction. The ratio of acetic anhydride to acetic acid in the product depends on the ratio of ethyl acetate to acetaldehyde in the initial mixture (Table 1).

Table 1. Formation of acetic anhydride by oxidation of acetaldehyde

Ethyl acetate: acetaldehyde in starting mixture	Acetaldehyde conversion, %	Acetic anhydride yield based on acetaldehyde, %
20 : 80	80	13.5
30 : 70	80	57
60 : 40	80	64
70 : 30	80	68.5

In practice, a 1 : 2 mixture of acetaldehyde and ethyl acetate is oxidized with the addition of 0.05 to 0.1 % cobalt acetate and copper acetate at 40 °C; the ratio of Co:Cu is 1:2. The ratio of acetic anhydride to acetic acid obtained is 56:44, whereas on oxidizing in the absence of ethyl acetate this ratio is only 20:80 [16]. The optimization of other reaction conditions can also lead to an increase in the acetic anhydride-acetic acid ratio. For example, at 55 °C and atmospheric pressure, a ratio of 80:20 was achieved [70]. At a higher temperature (62 – 90 °C, 200 – 300 kPa, acetaldehyde concentration in the final mixture of up to 40 %) a ratio of 75:25 was obtained at high aldehyde conversion [71].

Other suitable low-boiling solvents are methylene chloride, diisopropyl ether, cyclohexanone, or ethylidene diacetate. Nonvolatile esters also can be used as diluents, provided they do not have to be removed from the reaction zone. These include alkyl benzoates and alkyl phthalates [72].

The acetaldehyde oxidation is illustrated in Figure 5 by the process of Usines de Melle [73]. The gas mixture containing oxygen and acetaldehyde is pumped into the reactor (a). The oxidation takes place in the liquid phase and in the presence of catalysts. The reactor effluent is sent through a water-cooled condenser (b) constructed as a separator; non-condensable gases are sent to the packed column (c). Fresh acetaldehyde is introduced at the top of this column. The condensates from both the cooler (b) and the column (c) are distilled to obtain the product. Acetaldehyde is recovered from the branch stream (d) of the non-condensable gas. The other part of the gas flow is supplemented with air and returned to the reactor.

Figure 5. Acetaldehyde oxidation
a) Reactor; b) Condenser; c) Column; d) Branch stream (acetaldehyde recovery from non-condensable gas); e) Pump

Both towers and vessels are suitable as reactors if the heat of reaction can be dissipated. The process of Distillers Co. [69] is shown in Figure 6 as an example. The off-gas contains combustible low-boiling products, such as acetaldehyde, and solvents, such as methyl acetate and ethyl acetate. These can be flared off.

1.3.3. Carbonylation of Methyl Acetate

The thermal decomposition of acetic acid to form ketene requires a large amount of energy, a disadvantage of the conventional process for the production of acetic anhydride. Moreover, processes based on synthesis gas have been developed that allow the manufacture of products from coal that were hitherto produced from oil. An important example is the acetic acid produc-

tion process developed by Monsanto (→ Acetic Acid).

In 1973 Halcon patented the carbonylation of methyl acetate in the presence of a rhodium catalyst to form acetic anhydride [74]. However, the first plant (Eastman-Kodak Co., in Kingsport, Tenn., USA) using this process was not put into operation before 1983. Because no exact description of the process has so far been available, the following details are based upon information from the patent literature.

Methyl acetate is carbonylated to acetic anhydride in the liquid phase at a temperature of 160 – 190 °C and at a carbon monoxide partial pressure of 2 – 5 MPa:

$$CH_3COOCH_3 + CO \overset{\text{catal.}}{\rightleftharpoons} (CH_3CO)_2O \quad \Delta H = -94.8\ \text{kJ/mol}$$

The starting material, methyl acetate, can be produced by esterification of acetic acid with methanol. However, the methyl acetate obtained as a byproduct of the acetic acid synthesis from methanol and carbon monoxide is used preferably.

Catalysts. Rhodium [74] and nickel compounds [75], activated by CH_3I, HI, LiI, I_2, or other iodides, are particularly appropriate as catalysts. Rhodium catalysts have about a tenfold higher activity than nickel catalysts. The selectivity is higher than 95 % for both catalysts. Their activities and lifetimes are increased by mixing the carbon monoxide used for the synthesis with 2 – 7 % hydrogen. Chromium compounds have been used to shorten the induction phase of the reaction [74]. Kinetic investigations on the rhodium system have shown that the reaction is zero order with respect to the methyl acetate and carbon monoxide concentrations [76]. As possible byproducts, only acetic acid and ethylidene diacetate are mentioned.

The process also can start from dimethyl ether [74]. In this case, dimethyl ether is first carbonylated to methyl acetate, which is then converted to acetic anhydride by using more carbon monoxide in the same reactor:

$$CH_3OCH_3 \overset{CO}{\rightleftharpoons} CH_3COOCH_3 \overset{CO}{\rightleftharpoons} (CH_3CO)_2O$$

Process Description. The carbonylation method is illustrated by the Halcon process, shown schematically in Figure 7.

The methyl acetate is dried with acetic anhydride [77] and is sent to a reactor (b) lined with Hastelloy. Carbon monoxide is compressed (a) to the reaction pressure and then added. The reaction proceeds continuously at 175 °C in the presence of a catalyst consisting of $RhCl_3 \cdot 3\,H_2O$, CH_3I, and LiI. The considerable amount of heat generated by the reaction is removed by heat exchange and is used both for preheating methyl acetate and for the production of low-pressure steam. The unreacted carbon monoxide leaves the top of the reactor, is freed of condensable gases (methyl iodide, methylacetate, acetic anhydride, acetic acid, and ethylidene diacetate) by cooling (f), and is then recirculated. However, part of the circulating gas is separated from the main stream to avoid buildup of inert gases, which may be present in the carbon monoxide. The side stream is washed (g) with a countercurrent of pure acetic anhydride; in this way, the loss of methyl iodide in the offgas can be kept below 0.1 % [78]. This acetic anhydride is combined with the top condensate from the reactor (b), supplemented with fresh catalyst as required, and recirculated. The liquid reaction product leaving the reactor is expanded and subjected to flash distillation (c) [78]. To prevent catalyst decomposition, this distillation is performed in a carbon monoxide-hydrogen atmosphere at about 500 kPa [79]. At the bottom of the evaporator (c) a stream of liquid containing the catalyst is separated and recirculated into the carbonylation reactor. The vapor leaving the top of the evaporator is condensed and passed over adsorbers (d) to remove traces of rhodium and iodine compounds.

The raw anhydride is purified by distillation in three consecutive and continuously operating columns (e). In the first column, methyl iodide and methyl acetate are distilled overhead and recirculated to the carbonylation reactor. In the second column, acetic acid is distilled overhead. The bottom product is distilled in a third column to acetic anhydride of 99 % purity. The bottom product of the third column contains ethylidene diacetate and unidentified high-boiling components. To further reduce the iodide content of the pure anhydride, a solution of potassium acetate in acetic anhydride is added to the top of the column [80].

Other processes. Other processes and catalysts for the carbonylation of methyl acetate have

Figure 7. Halcon process for the production of acetic anhydride
a) Compressor; b) Carbonylation reactor; c) Evaporator; d) Adsorber; e) Distillation column; f) Condenser; g) Scrubber

been patented by various companies: Hoechst [81] (rhodium catalyst), Air Products and Chemicals Co.[82] (rhodium catalyst), Mitsubishi Gas and Chemical Co. [83] (nickel catalyst), and Rhône-Poulenc [84] (nickel catalyst). Several patents also describe the carbonylation of esters of higher alcohols and carboxylic acids. This reaction results in the formation of the corresponding mixed anhydrides [74], [83].

Environmental problems do not arise. The off-gas from the acetic anhydride production contains large quantities of carbon monoxide, some inert gases (nitrogen, rare gases, and carbon dioxide), and traces of hydrogen, methane, methyl iodide, and methyl acetate. It can be burned. There are no problems with waste water.

1.4. Analysis

A very reliable method for determining the content of acetic anhydride consists of mixing stoichiometric quantities of the sample and water, then heating carefully to reflux temperature. After completion of the reaction, two drops of concentrated sulfuric acid are added, and the mixture is boiled for 20 min to insure that the last traces of the anhydride have reacted. The anhydride content is calculated from the unused water, which is determined by the Karl Fischer method.

In the *aniline method* [85], the total acid content is first determined. After addition of aniline to a second sample, the aniline number is established with alkali and the acetic anhydride content determined from the difference.

A rapid determination of the anhydride content can be obtained from the refractive index. If the temperature remains constant to within $\pm 0.05\,^{\circ}\mathrm{C}$, the precision obtainable is ± 0.2 %. Gas chromatography also is recommended for purity determination. Analytical methods are discussed in detail in [86].

1.5. Quality Specifications

Acetic anhydride is marketed with more than 95 % purity; the normal product is over 98 % pure, but it is marketed also as over 99 % pure. The color number (APHA) should be below 10 (DIN 53409). The nonvolatile part should not exceed 0.003 %. The product also should contain as few substances as possible that reduce permanganate. According to American Chemical Society specifications, for example, a 2 g sample should not decolorize 0.4 ml of a 0.1 *N* potassium permanganate solution within 5 min. In particular applications, the impurities that

can be oxidized by potassium chromate are also of interest. They may not consume more than 200 ppm of oxygen. The contents of phosphate, sulfate, chloride, aluminum, and iron may not exceed 1 ppm each. Heavy metals should be absent.

1.6. Storage and Transportation

For storage and transportation of pure acetic anhydride, tanks made of aluminum, stainless steel (18 % Cr, 8 % Ni, and 2 % Mo), or polyethylene normally are used, although glass or enamel containers also may be employed. Iron is highly resistant to acetic anhydride, provided moisture is excluded. Therefore it is possible to use iron in the production and workup in certain instances, for example, in pumps and tanks.

Because there are no international arrangements for the storage of dangerous goods, the specifications of individual countries must be observed. Also, acetic anhydride (EG-no. 607–008–00–9) is subject to various industrial working regulations, for example, Appendix I, no. 1.1 of the EEC Guidelines.

Transportation. IMDG-Code, class 8, UN-no. 1715; United Kingdom: Blue Book: Corrosive, IMDG-Code E 8018; United States: DOT Safety Act, Title 46 and Title 49; Cor. M; Europe: RID, ADR, and ADNR: class 8, no. 21 e (from 1985: class 8, no. 32 e), RN 801, 2801, and 6801, respectively. International air transportation: IATA-DGR, class 8, UN-no. 1715, RAR art. no. 9, Cor. M.

1.7. Uses

Acetic anhydride is used chiefly as an acetylating and dehydrating agent; it is used on a large scale for the acetylation of cellulose. Other areas of application for acetic anhydride are:

1) The production of poly(methylacrylimide) hard foam, where acetic anhydride is used for binding the ammonia that is liberated on conversion of two amide groups to an imide group.
2) Acetylated plastic auxiliaries, such as glycerol triacetate, acetyl tributyl citrate, and acetyl ricinolate.
3) Explosives, particularly hexogen production (see Section 1.2.2.).
4) The production of certain types of brake fluids.
5) The production of auxiliaries for drilling fluids.
6) The detergent industry, for the production of cold – bleaching activators such as tetraacetylethylenediamine [12].
7) The dyeing industry, where acetic anhydride is used chiefly in mixtures with nitric acid as a nitrating agent. Here, the solvent and dehydrating properties of acetic anhydride are used.
8) In the preparation of organic intermediates, such as chloroacetylchloride, diacetyl peroxide, higher carboxylic anhydrides, acetates, and the boron trifluoride complex.
9) In the production of pharmaceuticals, such as acetylsalicylic acid, *p*-acetylaminophenol, acetanilide, acetophenacetin, theophyllin, acetylcholine chloride, sulfonamides, a number of hormones and vitamins, and the x-ray contrast agent 2,4,6-triiodo-3,5-diacetylamidobenzoic acid.
10) In the food industry, mainly in the acetylation of animal and plant fats, in order to obtain the desired solubilities; in the production of acetostearins, the edible packing materials; and to clarify plant oils.
11) Flavors and fragrances (production of esters and cumarin).
12) Herbicides such as metolachlor (Dual) and alachlor (Lasso).

2. Mixed Fatty Acid Anhydrides

2.1. Physical Properties

Important mixed anhydrides, that is, anhydrides with two different fatty acid radicals, are compiled in Table 2. The lower anhydrides can be distilled partly undecomposed at reduced pressure. At high temperature they disproportionate fairly rapidly into the symmetrical anhydrides. Only acetoformic anhydride distills (at 127 – 130 °C) at normal pressure, although with partial decomposition to acetic acid and carbon monoxide. The first four mixed anhydrides have odors very similar to pure acetic anhydride; acetic isovaleric anhydride has a fruitlike odor.

Table 2. Mixed fatty acid anhydrides

Anhydride	Formula	*bp* or *mp*, °C	Preferred production method (Section 2.3)
Acetoformic anhydride	$HCOOCOCH_3$	*bp* 32 (at 2.7 kPa)	3
Acetic propionic anhydride	$CH_3COOCOC_2H_5$	*bp* 25 – 27 (at 0.15 kPa) (decomposes at 30 °C)	3
Acetic butyric anhydride	$CH_3COOCO(CH_2)_2CH_3$	–	3
Acetic isobutyric anhydride	$CH_3COOCOCH(CH_3)_2$	–	3
Acetic valeric anhydride	$CH_3COOCO(CH_2)_3CH_3$	(decomposes above 130 °C)	3
Acetic isovaleric anhydride	$CH_3COOCOCH_2CH(CH_3)_2$	–	3
Acetic 2,2-dimethylpropanoic anhydride	$CH_3COOCOC(CH_3)_3$	–	3
Acetic hexanoic anhydride	$CH_3COOCO(CH_2)_4CH_3$	–	3
Acetic octanoic anhydride	$CH_3COOCO(CH_2)_6CH_3$	–	3
Acetic hexadecanoic anhydride	$CH_3COOCO(CH_2)_{14}CH_3$	*mp* 62.5 (decomposes on crystallization from polar solvents)	2,3
Acetic octadecanoic anhydride	$CH_3COOCO(CH_2)_{16}CH_3$	–	3
Butyric tetradecanoic anhydride	$CH_3(CH_2)_2COOCO(CH_2)_{12}CH_3$	*mp* 52.7	2
Hexanoic dodecanoic anhydride	$CH_3(CH_2)_4COOCO(CH_2)_{10}CH_3$	*mp* 42.4	2
Octanoic decanoic anhydride	$CH_3(CH_2)_6COOCO(CH_2)_8CH_3$	*mp* 16	2

2.2. Chemical Properties

Acetoformic anhydride [*2258-42-6*] acts as a formylation agent in acylation reactions. In the other mixed acetic – fatty acid anhydrides, the higher acyl group is more reactive; for example, in the reaction with benzene in the presence of aluminum chloride, compound (**5**) is formed preferably.

where R = alkyl.

Branching of the higher acyl group at its α position leads to a decrease in the yield of the acylbenzene (**5**) in favor of acetophenone (**6**) [87]. From acetic chloroacetic anhydride, mainly ω-chloroacetophenone is formed [87]. Changes in reaction conditions have little influence on the ratio of reaction products.

2.3. Production

Three processes are generally employed for producing mixed anhydrides:

1) The reaction of acetic anhydride with a higher organic acid [88].
2) Heating an acyl chloride with a fatty acid salt, usually a sodium or potassium salt [89–91].
3) Reacting ketene with a carboxylic acid [92–94].

The latter two processes are more useful than the first. According to the patent literature, mixed anhydrides also can be produced by carbonylating the corresponding esters (Section 1.3.3).

2.4. Uses

Acetoformic anhydride often is used as a formylating agent. Acetic propionic [*13080-96-1*] and acetic butyric [*7165-13-1*] anhydrides are used in the production of acylated cellulose.

3. Economic Aspects

Production data are given in Table 3. Annual capacity data for acetic anhydride are as follows: Western Europe (1978) 357 000 t, (1980) 362 000 t, (1996) 500 000 t; United States (1980) 905 000 t, (1982) 929 000 t, (1996) 1 000 000 t, (2001) 1 160 000 t. No data for the mixed anhydrides are available.

4. Toxicology and Occupational Health

In acute oral studies in rats, an LD_{50} value of 1780 mg/kg was determined for acetic anhy-

Table 3. Production of acetic anhydride (in kt) [95], [96], [97], [98]

	1961	1971	1974	1979	1980	1981	1982	1989	1990	1996	2001

dride. The dermal LD_{50} in rabbits is 4000 mg/kg [99]. Inhalation of 2000 ppm for 4 h causes death in rats [100]. The lowest published lethal concentration (LCLo) for a 4-h exposure of rats is 1000 ppm [101].

In rabbits, skin contact for 24 h causes only mild irritation [99]. These findings are in accordance with observations in humans. Tingling sensations followed by slight erythema 30 min after skin contact have been reported. Pain or vesication has not been observed [102]. In contrast to these observations, acetic anhydride is reported to cause wrinkling, whitening, and peeling, if it is not removed from the skin at once [103]. Acetic anhydride is a severe eye irritant [104]. In rabbits, 250 µg causes severe irritation. Human occupational exposure can cause lacrimation, conjunctivitis, photophobia [105], corneal burns with loss of vision [106], and iritis [107]. It is assumed that acetic anhydride penetrates the corneal epithelium rapidly without hydrolyzing and reaches the iris in concentrations high enough to cause iritis.

*Inhalation*can lead to asthmoid bronchitis with lung edema [108]. Human exposure to concentrations of 800 ppm cannot be tolerated for longer than 3 min because of the burning sensation in the nose and throat. Humans are believed to be generally more sensitive to the irritant effects of inhalation of vapors than animals [109]. *Ingestion* is followed by a burning pain in the stomach, nausea, and vomiting [110]. The acute irritant effects are caused partly by the hydrolysis of acetic anhydride to acetic acid, which itself is an irritant. The rate of hydrolysis depends on the water content of the tissues.

Systemic effects after repeated exposure are unlikely to occur because of the potent warning properties of acetic anhydride. The MAK and TLV are both 5 ppm (20 mg/m^3) [111], [112].

1. Introduction

Acetone, 2-propanone, dimethyl ketone, CH_3COCH_3, [*67-64-1*], is the first and most important member of the homologous series of aliphatic ketones. It is a colorless, mobile liquid widely used as a solvent for various polymers. Its largest application, however, is as an intermediate in the synthesis of methyl methacrylate, bisphenol A, diacetone alcohol, and other products.

Acetone was first manufactured by the dry distillation of calcium acetate [*62-54-4*]. Calcium acetate was originally a product of wood distillation, and later was obtained by fermentation of ethanol. Carbohydrate fermentation directly to acetone and butyl and ethyl alcohols displaced these processes in the 1920s. The carbohydrate route, in turn, was replaced in the 1950s and 1960s by the 2-propanol dehydrogenation process and by the oxidation of cumene to phenol [*108-95-2*] plus acetone. Together with direct propene oxidation, these methods account for over 95 % of the acetone produced worldwide.

2. Physical Properties

Acetone has the following physical properties: M_r 58.081; *bp* at 101.3 kPa, 56.2 °C; *mp* − 94.7 °C; relative density, d_4^0 0.81378, d_4^{15} 0.79705, d_4^{20} 0.7908; relative vapor density (air = 1) 2.0025; refractive index n_D^{20} 1.35868; critical temperature 235.0 °C, critical pressure 4.6 MPa (46 bar), critical density 0.278 g/cm^3; cubic expansion coefficient (18 °C) 1.43×10^{-3} K^{-1}; compressibility coefficient (18 °C) 1.286×10^{-6} kPa^{-1} (1.286×10^{-4} bar^{-1}).

Viscosity in mPa · s: 1.53 (− 80 °C), 0.71 (− 40 °C), 0.40 (0 °C), 0.32 (20 °C), 0.27 (40 °C). Surface tension in mN · m^{-1}: 38.1 (− 91.09 °C), 23.9 (15 °C), 23.3 (20 °C), 23.0 (24.8 °C), 22.0 (30 °C), 21.6 (42 °C).

Thermal properties: Specific heat capacity, c_p (20 °C) 2.135 kJ kg^{-1} K^{-1}; heat of fusion (− 95 °C) 98.47 kJ kg^{-1}; heat of vaporization (30 °C) 545.2 kJ kg^{-1}, (0 °C) 588.2 kJ kg^{-1}; molar entropy 0.2001 kJ mol^{-1} K^{-1}; heat of combustion 1804 kJ mol^{-1}; heat of formation (20 °C) 235.3 kJ/mol; thermal conductivity of the liquid 1.976 W m^{-1} K^{-1}.

Vapor Pressure in kPa: 24 (20 °C), 37.3 (30 °C), 56.0 (40 °C), 82.8 (50 °C), 114.8

(60 °C), 214.8 (80 °C), 372.8 (100 °C), 929.6 (140 °C).

Electrical properties: Electric conductivity (20 °C) $5.5 \times 10^{-8}\ \Omega^{-1}\ \mathrm{cm}^{-1}$; dipole moment (20 °C) 2.69 Debye; dielectric constant of the liquid 21.58 (0 °C), 22.64 (10 °C), 20.70 (25 °C), 19.38 (40 °C); dielectric constant of the vapor 1.0235 (24.8 °C), 1.0277 (29.8 °C).

At ambient temperature acetone is a clear, colorless liquid with a characteristic odor. It is miscible in all proportions with water and polar organic solvents, such as the lower molecular mass alcohols, carboxylic acids, and ethers. It is miscible in limited proportions with nonpolar solvents, such as hydrocarbons. Some azeotropic mixtures are shown in Tables 1 and 2 [3], [4].

Acetone dissolves many synthetic resins, e.g., nitrocellulose, acetylcellulose, poly(acrylate esters), and alkyd resins. It also dissolves most natural resins, fats, and oils.

3. Chemical Properties

Pure acetone is essentially inert to air oxidation and to diffuse sunlight under ambient conditions. Its chemical stability diminishes significantly in the presence of water. Acetone may react violently and sometimes explosively, especially in a confined vessel [5]. For example it is particularly sensitive to oxidizing agents, such as nitrosyl chloride [6] [*2696-92-6*], chromium trioxide [7] [*1333-82-0*], and hydrogen peroxide [8] [*7722-84-1*], or organic peroxides [9]. Mixtures of acetone with chloroform [*67-66-3*] may react violently in the presence of alkali [10]. Reaction even may be initiated by surface alkali on new glassware [11]. Acetone has a flash point of −17 °C (closed cup). Flammability limits in air are: lower 2.13 vol %, upper 13 vol %; autoignition temperature 465 °C. The flammability of acetone can be reduced by mixing it with less flammable and/or less volatile solvents [12]. Fires have been started during recovery of acetone from air by adsorption on activated carbon when air flow was too low to effectively remove the heat generated by surface oxidation [13].

Acetone undergoes typical carbonyl reactions with particular ease. Acid- or base-catalyzed self-condensation produces the dimers diacetone alcohol and mesityl oxide and the cyclic trimer isophorone.

Under strongly basic conditions hydrogen cyanide adds to acetone to form 2-cyano-2-propanol (acetone cyanohydrin), an important intermediate in the manufacture of methyl methacrylate and other methacrylate esters (Section 8.1).

In liquid ammonia solution acetone condenses with acetylene [*74-86-2*] in the presence of catalytic amounts of alkali metals to form 2-methyl-3-butyn-2-ol [*115-19-5*], an intermediate in the synthesis of isoprene [14] [*563-46-2*]. Catalytic hydrogenation of acetone yields 2-propanol [*67-63-0*]. Pyrolysis produces methane [*74-82-8*] and ketene [*463-51-4*], a powerful acetylating agent. A more economical source of ketene, however, is the pyrolysis of acetic acid, which produces ketene and water.

Reductive ammonolysis of acetone yields isopropylamine [*75-31-0*]. Condensation with 2 mol phenol in the presence of an acidic catalyst yields bisphenol A (Section 8.2), an important

monomer used in the manufacture of polycarbonate resins.

Perchlorination yields hexachloroacetone [*116-16-5*], which is cleaved into chloroform [*67-66-3*] and sodium trichloroacetate [*650-51-1*] upon treatment with sodium hydroxide.

4. Production

Approximately 83 % of the acetone produced worldwide is manufactured from cumene as a coproduct with phenol. In the United States and Western Europe dehydrogenation of 2-propanol is also important, whereas in Japan catalytic oxidation of propene is used as a second process. Cumene, 2-propanol, and propene together as starting materials account for over 95 % of the acetone produced worldwide. Because propene is used in the manufacture of both cumene and 2-propanol, propene is the ultimate raw material for the production of acetone.

Small amounts of acetone are made by oxidation of *p*-diisopropyl benzene and of *p*-cymene. Coproducts from these reactions are hydroquinone and *p*-cresol, respectively. Acetone is also produced by propene oxidation and as a byproduct of acetic acid manufacture.

Fermentation of cornstarch and molasses to acetone and 1-butanol was important in the past. It is believed to be practiced today to a limited extent in several countries.

4.1. Cumene Oxidation (Hock Process)

(Fig. 1)

Propene [*115-07-1*] is added to benzene [*71-43-2*] to form cumene [*98-82-8*], which is then oxidized by air to cumene hydroperoxide (**1**), and cleaved in the presence of an acid catalyst. Phenol [*108-95-2*] and acetone produced in the process are recovered by distillation.

The alkylation of benzene by propene proceeds under typical Friedel – Crafts conditions. In 1996, a number of processes using zeolite catalysts came on-stream. The cumene produced is purified by chemical means and refined by distillation to 99.9 % minimum purity. Oxidation-grade cumene must meet strict quality standards.

Figure 1. Cumene phenol – acetone process (Allied)

AMS = α-methylstyrene

Table 3. Specifications for oxidation-grade cumene (zeolite process) [15]

Property	ASTM test	Specification
Appearance		Clear, colorless liquid
Color, Pt – Co scale	D1209-79	15 max.
$d_{15.5}^{15.5}$	D891-59	0.864 – 0.867
Acid wash color, W scale	D848-62	2 max.
Sulfur compounds	D853-47	Free from H_2S and SO_2
Copper corrosion	D849-47	No iridescence, gray or black
Distillation range	D950-56	1.0 °C max.
Cumene content		99.93 % min.
Phenolics content		5 ppm max.
Cumene hydroperoxide content		200 ppm max.
Sulfur content		0.1 ppm max.

The newer zeolite-based processes have led to slightly tighter specifications (Table 3) [15].

Cumene Oxidation. The oxidation of cumene is a free-radical chain reaction [16]. The chain initiator is cumene hydroperoxide, the main product of the reaction. The rate of oxygen consumption can be approximated by the following expression:

$$\frac{-\mathrm{d}c_{\mathrm{O_2}}}{\mathrm{d}t} = k_{\mathrm{p}} \cdot c_{\mathrm{RH}} \sqrt{\frac{2k_{\mathrm{i}} c_{\mathrm{ROOH}}}{k_{\mathrm{t}}}}$$

c_{RH} and c_{ROOH} are the concentrations of cumene and cumene hydroperoxide, respectively; k_{i}, k_{p}, and k_{t} are the rate constants for chain initiation, propagation, and termination.

The expression shows that the rate of oxidation is zero in the absence of cumene hydroperoxide. This is not exactly true, because the expression is only an approximation; but the oxidation of cumene does require long induction periods when starting with pure cumene. Consequently, the industrial oxidation always is carried out in a series of continuous reactors; the concentration of cumene hydroperoxide is at least 8 wt % in the first reactor. Because the sum of c_{RH} and c_{ROOH} remains roughly constant during the reaction, the rate of reaction cannot increase indefinitely as c_{ROOH} increases. The maximum rate is achieved at approximately 35 wt % cumene hydroperoxide.

Besides cumene hydroperoxide, both dimethylphenylmethanol and acetophenone are also formed as byproducts during this oxidation. These arise from a secondary chain reaction that proceeds in parallel with the main chain. Byproduct formation is accelerated as the concentration of cumene hydroperoxide increases. For these reasons, most plants operate between 25 and 40 wt % in the last oxidation reactor.

A minor but significant byproduct of the oxidation is dicumyl peroxide [*80-43-3*]. This arises during the termination of the chain reaction. Dicumyl peroxide also contributes to chain initiation [17], but to a much lesser degree than cumene hydroperoxide. Other minor byproducts are formaldehyde and formic acid, which are produced along with acetophenone by methyl group degradation.

The oxygen needed for cumene oxidation is supplied by air. Use of pure oxygen has been suggested [18] but is disfavored by both economic and safety considerations [19]. At low initiation rates, the rate of the reaction is essentially independent of the oxygen concentration at a partial pressure of oxygen over 33 kPa (0.33 bar) [20]. A detailed study of the rate of oxygen uptake in a bubble column as a function of temperature and partial oxygen pressure has been made [21]. The study served as a basis for a mathematical model of the oxidation [22], [23].

Two cumene oxidation processes are used in the United States, which with minor variations are practiced also in the rest of the world [19], [22]. One process was developed by Hercules and licensed by Kellogg (previously BP/Hercules) and GE/Lummus [24]. The other process was developed by Allied and licensed by Allied/UOP [25–28].

In both processes several reactors are employed in series. Fresh and recycled cumene are fed to the first reactor, which may operate at 8 – 12 wt % cumene hydroperoxide. The concentration increases by 4 – 8 wt % in each successive reactor; the last reactor may operate at 25 – 40 wt % cumene hydroperoxide. Fresh air

is pumped in parallel to each reactor and vented at the top after removal of organic vapors.

In the *Hercules process*, the oxidation of cumene is carried out at approximately 620 kPa (6 bar)/90 – 120 °C, in the presence of a sodium carbonate buffer [29]. Under these conditions the residence time in the oxidizer train is 4 – 8 h and the hydroperoxide molar selectivity 90 – 94 %. The spent air is first passed through water cooled and refrigerated condensers in series to remove organic vapors, and is finally vented. The condensate is returned to the oxidizers after treatment [29].

In the *Allied/UOP process* (Fig. 1) the oxidation is carried out at atmospheric pressure. No buffer or promoter is added, but great care is taken to wash all streams recycled to the oxidizer with alkali and water [27]. Temperature is maintained at 80 – 100 °C. Residence time in the oxidizer train is 10 – 20 h and hydroperoxide molar selectivity is 92 – 96 %. Spent air is vented after organic vapors are removed by condensation followed by activated carbon adsorption. The recovered materials are washed with aqueous sodium hydroxide and water, then returned to the oxidizers.

The oxidation of cumene generates approximately 116 kJ of heat per mole of cumene oxidized [30]. Part of this heat is carried to the condensers by organic vapors (this part is larger in the Allied/UOP process because of the lower operating pressure). The rest is removed by heat exchangers.

In both processes cumene hydroperoxide is concentrated to over 80 wt % by evaporation of excess cumene. In the Hercules process the oxidate is washed with water prior to distillation in order to remove the buffer added during oxidation.

Cumene Hydroperoxide Cleavage. Cumene hydroperoxide [*80-15-9*] is cleaved to phenol and acetone in the presence of catalytic amounts of a strong acid. The acid most commonly used is sulfuric acid. Sulfur dioxide is used as catalyst in the Allied/UOP process. Several patents claim the use of solid acids as catalysts for the decomposition [31]. Strongly acidic resins have been used to that effect in the Soviet Union [32]. However, all commercial units use strong mineral acids or SO_2, which generates sulfuric acid in situ, as catalysts.

The cleavage proceeds through an ionic mechanism and releases approximately 252 kJ/mol of cumene hydroperoxide decomposed [30]. The reaction rate accelerates rapidly with increasing temperature. Consequently, decomposition of cumene hydroperoxide commonly is carried out in a continuously stirred reactor in which the steady-state concentration of cumene hydroperoxide is maintained at a low level. The heat released by the reaction can be used to estimate the concentration of hydroperoxide present in the reactor at any time [33].

The molar selectivity of the cleavage to phenol and acetone is higher than 99.5 % at temperatures below 70 °C, but it decreases at higher temperatures as increasing amounts of dimethylphenylmethanol and acetophenone (in addition to those present in the cumene oxidate) are formed (Table 4) [28].

Table 4. Formation of byproducts during cumene hydroperoxide decomposition ∗

Temp. °C	Molar ratio (byproducts/phenol) × 100	
	DMPM equivalents∗∗	Acetophenone
70	0.36	0.06
90	0.61	0.06
110	1.24	0.15
122	2.19	0.25
146	5.04	0.69

∗ Pure cumene hydroperoxide added to phenol – acetone – cumene solution containing initially 0.5 wt % water and 100 ppm sulfuric acid; data from [28].
∗∗ Sum of dimethylphenylmethanol, α-methylstyrene, and their condensation products.

Acetone produced during the cleavage of cumene hydroperoxide can react further. Oxidation by cumene hydroperoxide forms hydroxyacetone [34] to the extent of 0.2 – 0.5 % of acetone present. Self-condensation catalyzed by acid results in diacetone alcohol and mesityl oxide. Conversion of acetone to these condensates is normally below 0.1 % but may increase upon protracted exposure to strong acid. For example, when the cumene hydroperoxide cleavage was carried out with refluxing acetone using a sulfonic acid resin as catalyst, approximately 1.7 % of acetone was transformed to diacetone alcohol and mesityl oxide [32].

Under the conditions of the cumene hydroperoxide cleavage, dimethylphenylmethanol is dehydrated to α-methylstyrene (**2**) and also forms undesirable condensates.

2

Compound (**2**) may be either hydrogenated [35] to cumene and recycled, or recovered and sold.

In the *Hercules process*, the cumene hydroperoxide decomposition is carried out in a constant-flow, stirred tank reactor in the presence of sulfuric acid or another strong mineral acid [19], [28]. The acid is added to the reactor as an acetone solution. The reactor temperature is maintained below 95 °C by refluxing approximately 2.8 kg acetone per kilogram cumene hydroperoxide. The ratio of the quantity of reflux to the quantitiy of hydroperoxide fed is used as a monitor of the cleavage reaction [19].

In the *Allied/UOP process* the cumene hydroperoxide cleavage is carried out at 60 – 80°C in a pressurized, constant-flow, back-mixed reactor. Temperature is controlled by means of heat exchangers in the loop. The catalyst is either sulfuric acid or sulfur dioxide. Up to 5 wt % cumene hydroperoxide remains unreacted. Under these conditions, dimethylphenylmethanol combines with cumene hydroperoxide to form dicumyl peroxide (**3**) [*80-43-3*], which upon subsequent heating to 110 – 140 °C in a short-residence-time plug-flow reactor is cleaved into phenol, acetone, and α-methylstyrene.

3

This sequence suppresses the formation of condensates by approximately 50 %. Variants of this two-stage process have been patented [36].

Product Separation. In the *Hercules process* the cleavage mixture is neutralized with base and then fed to a separation column. The overheads from this column contain acetone, α-methylstyrene, and cumene; acetone is recovered by distillation, and α-methylstyrene is hydrogenated without prior separation from cumene. This cumene stream is then recycled to the oxidizers. Phenol from the bottoms of the separation column is recovered by distillation.

In the *Allied/UOP process* the cleavage mixture is treated with an ion-exchange resin to remove the acid catalyst and then is distilled. Acetone is removed first in a crude acetone column and purified by distillation with steam in an acetone-refining column. Cumene, α-methylstyrene, and phenol are recovered by sequential distillation of the bottoms from the crude acetone column. Cumene is recycled to the oxidizers after it has been washed with alkali, and α-methylstyrene is marketed.

4.2. Dehydrogenation of 2-Propanol

The hydration of propene [*115-07-1*] gives 2-propanol [*67-63-0*], which is then dehydrogenated to acetone. In the United States a C_3 stream containing 40 – 60 % propene is used for the manufacture of 2-propanol (**4**).

4

The dehydrogenation of (**4**) is endothermic by 66.6 kJ/mol at 327 °C. The equilibrium constant, K_p (bar), obeys the following equation [37]:

$$\log K_p = -2764/T + 1.516 \log T + 1.765$$

The main side reaction is the dehydration of 2-propanol to propene. Other competing reactions are the self-condensation of acetone to diacetone alcohol, which leads to further condensation products.

A large number of catalysts for 2-propanol dehydrogenation have been studied, including copper, zinc, and lead metals, as well as metal oxides, e.g., zinc oxide, copper oxide, chromium-activated copper oxide, manganese oxide, and magnesium oxide. Inert supports, such as pumice, may be used.

Highly active catalysts are the precious metals platinum and ruthenium [39] or 0.25 % platinum on sodium-activated alumina [40]. These catalysts are particularly effective for the dehydrogenation of aqueous 2-propanol, which is obtained by hydration of propene.

All catalysts gradually lose activity because of a buildup of carbon deposits, so the operating temperature is increased as the catalyst ages.

The catalyst is regenerated periodically by burning out the deposits. A good catalyst lasts for several months.

In a typical process, the azeotropic mixture of water and 2-propanol (87.8 wt % 2-propanol) is evaporated (sometimes using steam as carrier) and fed to a catalyst bed in a reactor specially designed for effective heat transfer. Hydrogen, produced downstream, may be mixed with the feed to prevent catalyst fouling. The reactor consists of a multitude of 2.5-mm steel tubes heated by oil, high-pressure steam, hot gases, or molten salts. The reaction produces hydrogen (> 99 % purity) as a valuable byproduct. This is separated by condensing all other components. Acetone is separated by distillation. The process is illustrated in Figure 2. Typical operating conditions are shown in Table 5.

4.3. Propene Oxidation [43], [44]

Direct oxidation of propene (Wacker – Hoechst process) currently is practiced only in Japan. A mixture of acetone (92 % selectivity) and propionaldehyde (2 – 4 % selectivity) is produced.

$$CH_3CH{=}CH_2 + 1/2\ O_2 \xrightarrow{\text{catalyst}} CH_3COCH_3 + CH_3CH_2CHO$$

The process is analogous to the oxidation of ethylene to acetaldehyde by the Wacker process. The catalyst solution typically contains 0.045 M palladium(II) chloride, 1.8 M copper(II) chloride, and acetic acid [45]. The reaction usually is carried out in two alternating stages. In the first stage, air is used to oxidize the metal ions to the +2 oxidation state. In the second, air is removed and propene added. Palladium(II) oxidizes propene, and the resulting palladium(I) is reoxidized by the pool of copper(II). Reaction conditions are 1 – 1.4 MPa (10 – 14 bar) and 110 – 120 °C. Propene conversion is higher than 99 %.

Besides propionaldehyde, chlorinated carbonyl compounds and carbon dioxide also are

Table 5. Gas-phase dehydrogenation of 2-propanol

Company	Catalyst	Temperature, °C	Pressure, kPa	Conversion, %	Selectivity, %	Yield, %	Reference

formed. Acetone and the byproducts are removed from the catalyst solution by flash evaporation with steam and separated by fractional distillation. Propionaldehyde (*bp* 49 °C) distills in one column and acetone (*bp* 56 °C) distills in the other.

4.4. Oxidation of 2-Propanol [46]

In the absence of catalysts 2-propanol reacts with oxygen via a free-radical reaction to form acetone and hydrogen peroxide.

$$CH_3CH(OH)CH_3 \xrightarrow{O_2} CH_3COCH_3 + H_2O_2$$

Until the mid-1980s the Shell process used hydrogen peroxide for the manufacture of glycerol from propene. The theoretical yield of acetone based on glycerol produced is 1.26 kg/kg. Acetone yields of about 90 % of theoretical were obtained.

4.5. Oxidation of *p*-Diisopropyl Benzene

Acetone is coproduced with hydroquinone [*123-31-9*] from *p*-diisopropylbenzene [*100-18-5*] in a process analogous to the phenol – acetone production from cumene.

In the Goodyear process [47] *p*-diisopropylbenzene is oxidized by oxygen in the presence of caustic. The *p*-diisopropylbenzene dihydroperoxide (**5**) [*3159-98-6*] formed is crystallized and washed with benzene. It is then dissolved in acetone and cleaved to hydroquinone and acetone in the presence of sulfuric acid. Next the acid is neutralized with ammonia and the ammonium sulfate formed is filtered. Acetone is recovered by distillation from the reaction mixture. Some of this acetone is recycled to the cleavage section while the rest passes through a finishing column for purification to at least 99.5 %. Eastman Chemical and Goodyear Tire & Rubber Company use this process in the United States. Annual US capacity is estimated to be 18 – 20 t/a. Sumitomo Chemical Company and Mitsui Petrochemical Industries of Japan use a similar process to produce *p*-cresol from cymene. Their annual capacity of acetone byproduct is 48 000 t.

4.6. Fermentation of Biomass

The fermentation of cornmeal or molasses by various members of the *Clostridium* genus yields a mixture of 1-butanol, acetone, and ethanol in 2 % overall concentration. The products are recovered by steam distillation and then fractionated.

The process was started during World War II to provide acetone needed for the manufacture of cordite. The last operating plant in the United States (Publicker Industries) closed in 1977.

The mixture of butanol, acetone and ethanol produced has been considered for use as a gasoline substitute in France [48]. Research aimed at increasing the concentration of useful products obtained in the process was carried out in the United States in the early 1980s [49]. The future of the fermentation process is tied to the availability of petrochemical feedstocks. High oil prices during the oil crises of the mid to late 1970s led to renewed interest in the process. Given the low oil prices of the 1990s and the ready availability of feedstocks at reasonable prices, it does not appear that these processes can compete under current conditions.

5. Environmental Protection

Because approximately 70 % of acetone is produced from cumene, a close examination of this process is warranted. Potential pollution sources in a phenol – acetone plant are emissions to the atmosphere and liquid discharge. Atmospheric emissions from the phenol – acetone process in the late 1970s have been estimated [29]. However over the past 20 years, and particularly in the 1990s with the renewal of the Clean Air Act, these emissions have been reduced significantly.

Aqueous streams containing significant amounts of organic substances arise from the

various wash operations and sumps at the plant. Insoluble material is recovered by decantation. Phenol and acetone (0.5 – 3 wt % each) are the most abundant organic compounds remaining in the water after decantation. There are also minor quantities (0.001 – 0.1 wt %) of cumene, α-methylstyrene, dimethylphenylmethanol, acetophenone, formaldehyde, formic acid, and various condensates. Of these compounds, phenol, formaldehyde, and formic acid are listed as hazardous substances in the U.S. Federal Water Pollution Control Act [50], but only phenol is present in sufficient quantities to require removal. Phenol is removed from the aqueous solution by solvent extraction, steam stripping, or adsorption on carbon or resins [51] and subsequently is recovered. The recovered phenol is valuable enough to pay for the capital and operating expenses of phenol abatement. Residual phenol in the water (10 – 500 ppm) is destroyed by biological degradation.

The federal regulatory status of acetone has changed. Acetone was granted VOC-exempt status by EPA on June 16, 1995 [53]. As of August, 1997, forty-four states had promulgated similar state rules. In states that have not yet promulgated state exemptions, acetone may technically still be regulated as a VOC. Acetone is not listed as a hazardous air pollutant (HAP) under section 112(b) of the Clean Air Act (CAA), or as an extremely hazardous substance under EPCRA Section 302. Acetone is also not listed as a priority pollutant under the Clean Water Act. It has been approved under the CAA as a substitute for ozone-depleting substances. Acetone was removed from the Federal Emergency Planning and Community Right-to-Know Act (EPCRA Section 313) list in June of 1995. Acetone is not regulated as a known or suspected carcinogen, and the National Toxicology Program (NTP) has recommended against testing for carcinogenicity because of its low toxicity and absence of any evidence supporting the carcinogenic potential of acetone.

Acetone is listed as a "U" waste under the Resource Conservation and Recovery Act (RCRA) based on its ignitability. "U" wastes are commercial chemicals that must be treated as hazardous wastes when discarded. Because of its RCRA listing it is included in the list of hazardous substances in the Superfund statute (Comprehensive Environmental Response, Compensation, and Liability Act).

6. Quality Specifications and Analysis

Acetone is produced industrially in relatively high purity, the main impurity being water. Table 6 summarizes the quality requirements for commercial 99.5 % acetone. Methods for preparing very high purity acetone from the commercial material are given in reference [54].

Gas chromatography is the most widely used method for the quantitative analysis of acetone. For example, good separation of acetone from other low-boiling organic compounds can be obtained on a 30 m × 0.32 mm Carbowax capillary column. Extensive data on packed column separations are compiled in [55]. Infrared (carbonyl absorption, 1711 cm^{-1}) and ^1H NMR (singlet at ca. 1.05 ppm) spectroscopy may be used for both qualitative and quantitative analysis.

Table 6. Standard specifications for acetone, ASTM D329-90

Property	ASTM test	Specification
Relative density	D268	
20/20 °C		0.7910 – 0.7930
25/25 °C		0.7865 – 0.7885
Color	D1209	≤ 5 on platinum-cobalt scale
Distillation range	D1078	1.0 °C, including 56.1 °C
Nonvolatile matter	D1353	≤ 5 mg/100 mL
Odor	D1296	characteristic, nonresidual
Water	D1364	≤0.5 wt % ∗
Acidity (as acetic acid)	D1613	≤0.002 wt %
Water miscibility	D1722	passes test
Alkalinity (as ammonia)	D1614	≤0.001 wt %
Permanganate time	D1363	≥30 min at 25 °C

∗ This water limit ensures that the material is miscible without turbidity with 19 volumes of 99 % heptane at 20 °C (ASTM D1476).

7. Storage and Transportation

Acetone has a low flash point; therefore, all shipping and storage containers must carry a red, diamond shaped "flammable liquid" label. Strict precautions should be taken to guard against fire hazards whenever acetone is handled. All wiring should be installed as described in Article 500 of the U.S. National Electrical Code or corresponding regulations in other countries. Explosion-proof motors, switches, etc., should be used. Accumulation of static electricity should be prevented by grounding and humidity control. Use of spark-resistant tools is recommended. Small fires may be controlled by use of carbon dioxide or dry chemical extinguishers. "Alcohol"-type foam should be used on larger fires; water spray will reduce the intensity of the flame.

Contact of acetone with oxidants should be avoided because it may lead to explosion [5]. Contamination with chlorinating agents may lead to the formation of toxic chloroketones. Prolonged exposure to direct sunlight may result in the formation of carbon monoxide. Packaging requirements for acetone are described in paragraph 49 CFR 173.242 (bulk), Bulk Packaging with Packaging for Certain Medium Hazard Liquids and Solids, Including Solids with Dual Hazards [56]. Transportation of acetone is covered in paragraph 49 CFR 172.101, Table of Hazardous Materials, of the Department of Transport Regulations [57]. The international transportation codes are IMDG Code D 3102; UN no. 1090; CFR 49, 172.101; RID (ADR, ADNR): Class 3, IATA: flammable liquid. The quantity of acetone in one package may not exceed 5 L in plastic, metal or aluminum, 1 L in glass, or 0.5 L in a glass ampoule in a passenger aircraft. The quantity of acetone in one package may not exceed 60 L in a cargo plane.

8. Uses

The main uses of acetone are as a chemical intermediate and as a solvent. The estimated 1995 acetone consumption by area of application in the USA is shown in Table 7 [59].

Table 7. Estimated 1995 US acetone consumption by area of application [59]

Use	Acetone used, 10^3 t
Acetone cyanohydrin/methacrylates	500
Bisphenol A	203
Aldol chemicals	140 (total)
Methyl isobutyl carbinol	35
Methyl isobutyl ketone	76
Others	22
Solvent use	191
Other uses	90
Total	1124

8.1. Methyl Methacrylate

Acetone is condensed with hydrogen cyanide to form acetone cyanohydrin (**6**) (see Section 11.1), which is next hydrolyzed with sulfuric acid to methacrylamide sulfate (**7**).

Further reaction with methanol yields methyl methacrylate (**8**) [*80-62-6*]. Approximately 0.70 kg of acetone is required per kilogram of methyl methacrylate produced.

Higher methacrylate esters may be produced either by transesterification of methyl methacrylate or by esterification of methacrylic acid (**9**) [*79-39-0*]; the latter is made by hydrolysis of methacrylamide sulfate:

At the end of 1995 there were 22 plants manufacturing MMA in the United States, Western Europe, and Japan. Five basic process routes have been commercialized: The acetone cyanohydrin route; two-stage oxidation of isobutylene to methacrylic acid followed by esterification; two-stage oxidation of *tert*-butyl alcohol to methacrylic acid followed by esterification; hydroformylation of ethylene to propionaldehyde, condensation with formaldehyde

to methacrolein, oxidation, and esterification (BASF); and ammoxidation of *tert*-butyl alcohol to methacrylonitrile, which is hydrolyzed to methacrylamide sulfate and then esterified to MMA (Asahi). One new route has been announced by Mitsubishi Gas Chemicals, which is a recycle version of the acetone cyanohydrin route. A 41×10^3 t/a plant to make MMA and MAA started up in 1997. Worldwide production of MMA in 1996 was about 1682×10^3 t [60].

8.2. Bisphenol A (→ Phenol Derivatives)

Bisphenol A (**10**), 4,4′-isopropylidenediphenol [*80-05-7*] is manufactured by condensation of 2 mol phenol with 1 mol acetone in the presence of an acid catalyst:

10

Approximately 0.28 kg of acetone is required per kilogram of bisphenol A. In the 1990s, bisphenol A has had the fastest growing demand of the phenol derivatives. Four US. companies produce bisphenol A: Shell (Deer Park, Texas), General Electric (Mount Vernon, Indiana), Dow (Freeport, Texas), and Aristech (Haverill, Ohio). Estimated worldwide usage in 1995 was 1600×10^3 t [61].

8.3. Aldol Chemicals (see Section 11.2, also → Ketones)

These chemicals are produced by condensation of acetone. Two moles of acetone form 1 mol of diacetone alcohol, 4-hydroxy-4-methyl-2-pentanone (**11**) [*123-42-2*]. Subsequent dehydration yields mesityl oxide, 4-methyl-3-penten-2-one (**12**) [*141-79-7*]. Hydrogenation of (**11**) yields 2-methyl-2,4-pentanediol (**13**) [*107-41-5*]. By hydrogenation of (**12**) methyl isobutyl ketone (**14**) [*108-10-1*] is available; further hydrogenation produces 4-methyl-2-pentanol (**15**) [*108-11-2*]. Three moles of acetone are condensed to 1 mol of isophorone, 3,5,5-trimethyl-2-cyclohexen-1-one (**16**) [*78-59-1*].

Approximately 1.25 kg of acetone is used per kilogram of methylisobutyl ketone produced. The US 1996 production of ca. 100×10^3 t of MIBK consumed ca 75×10^3t of acetone. The US manufacturers are: Eastman (Kingsport, Tennessee), Shell (Deer Park, Texas), and Union Carbide (Institute, West Virginia) [62]. Methyl isobutyl ketone is used as a solvent for nitrocellulose lacquers, vinyl polymers, and acrylic resins [62].

Diacetone alcohol, mesityl oxide, and isophorone are used mainly as solvents. Their use has diminished in the USA because of their status as photochemically reactive solvents under Rule 66 of Los Angeles County [52]. The primary use of 4-methyl-2-pentanol is for ore flotation, and 2-methyl-2,4-pentanediol is used in hydraulic fluids and printing inks.

8.4. Solvent Uses

Acetone is used as a solvent for paints, varnishes, and lacquers. It is also used as a wash solvent for these materials and as a spinning solvent in the manufacture of cellulose acetate. A small amount of acetone is used as a solvent for acetylene. Approximately 191×10^3 t of acetone was consumed in direct solvent applications. The major solvent market for acetone is in paints and coatings. Consumption of acetone in these applications increased by 9×10^3 t in 1995 because of its delisting as a VOC.

The pharmaceutical industry is also a large consumer of acetone for the manufacture of pharmaceuticals, vitamins, and cosmetics. In 1995 acetone consumption in pharmaceutical and cosmetic applications was $(36-43) \times 10^3$ t.

The removal of acetone from the VOC list has made it more attractive as a solvent, particularly for replacing other chemicals on the VOC list. Following the EPA's August 1995 action, eight states automatically delisted acetone as a volatile organic compound. As of August, 1997, forty-four states had promulgated similar state rules.

9. Economic Aspects

The United States acetone capacity by manufacturer and production process can be found in [63]. World capacity data are given in Table 8 [59]. The United States acetone production for the last two decades is summarized in Table 9 [59]. Worldwide production in 1994 was: USA 1281×10^3 t/a; Western Europe 1200×10^3 t/a; Asia 746×10^3 t/a.

Table 8. World acetone capacity, 1995 [59], [64]

Location	Capacity, 10^3 t
United States	1281
Mexico	22.3
Western Europe	1200
Japan	475
Other Asia	271.4
Others	592
World total	3842

Table 9. United States acetone production, 10^3 t [59]

Year	From 2-propanol	From cumene	Other	Total
1970	379	329	26	734
1975	312	433		745
1980	250	693		943
1985	41	768	3	812
1990	70	972	17	1059
1994	73	1110	20	1203

In 1995 the phenol process accounted for 83 % of all acetone made and 9 % was derived from 2-propanol; only 8 % was produced by all other processes (66×10^3 t/a from propene oxidation in Japan).

The economics of acetone are unusual. The bulk of acetone is made as a coproduct with phenol. Consequently, phenol demand determines to a large extent the availability of acetone. Fortunately acetone serves to some extent the same markets as phenol does. These are mainly the automotive and housing markets. As a result, when economic conditions place a demand on phenol, acetone demand also increases. However, an unusually steep demand for phenol may render acetone an overabundant byproduct [63].

Because the single largest use of acetone is as an intermediate in the manufacture of methacrylates, alternate routes to methacrylates, such as the oxidation of C_4 hydrocarbons, are a potential threat to acetone. When C_4 hydrocarbon stocks are in demand for the manufacture of gasoline additives, they are not likely to be used for acrylate manufacture. However, production of methacrylate by oxidation of C_4 hydrocarbons started in Japan in 1982 [65].

Dehydrogenation of 2-propanol accounted for approximately 80 % of US acetone produced in 1960. As the cumene-based process expanded, the 2-propanol contribution shrank to 52 % in 1970, 27 % in 1980, and 6 % in 1994. If acetone supply does outstrip demand, it is likely that production based on 2-propanol will be further curtailed.

Phenol manufacturing processes that do not coproduce acetone have been developed partly because of fears that there will be a supply/demand imbalance between phenol and acetone. DSM and its licensees produce phenol by the air oxidation of toluene via benzaldehyde and benzoic acid. Subsequently, benzoic acid is decomposed to phenol with a copper catalyst. This route provides phenol, benzaldehyde, and benzoic acid. Mitsui Petrochemical has developed a recycle scheme for converting the acetone byproduct from the cumene hydroperoxide rearrangement back to propylene for feed to the front end of the cumene process. Solutia (formerly Monsanto) and the Boreskov Institute of Catalysis have developed a catalyst capable of oxidizing benzene in high yield with nitrous oxide to give directly phenol. The key to this process is the inexpensive nitrous oxide available as a byproduct from the manufacture of adipic acid. Asahi Chemical has patented a process in which benzene is partly hydrogenated to cyclohexene. The cyclohexene is hydrolyzed to cyclohexanol or oxidized to cyclohexanone; dehydrogenation then gives phenol [66].

10. Toxicology and Occupational Health

Acetone is one of the least toxic industrial solvents [67]. However, exposure to vapor at high concentration should be avoided because it can produce temporary narcosis and cause slight eye irritation. Repeated skin contact with the liquid defats the skin and may cause dermatitis. The liquid is also irritating to the eyes and may cause moderate corneal injury.

The ACGIH [68] has adopted a time-weighted average threshold limit value (TLV-TWA) of 750 ppm, 1.78 g/m^3, and a short-term exposure limit (TLV-STEL) of 1000 ppm, 2.375 g/m^3, for acetone. OSHA regulations [69] set a limit of 2.4 g/m^3. However, the ACGIH has issued a notice of intended change to lower the TLV to 500 ppm (1.19 g/m^3), and the STEL to 750 ppm (1.78 g/m^3) [70]. Exposure limits (TLV-TWA) adopted by the main industrial countries are shown in Table 10 [71]. The odor threshold of acetone is 48 mg/m^3 provided desensitization has not occurred. Animal studies have shown acetone to be relatively nontoxic [67], [71].

Table 10. Time-weighted average threshold limits for acetone [71]

Country	Limit, mg/m^3
Australia	1780
Belgium	1780
Germany	2400
Italy	1000
Japan	470
Netherlands	1780
Former Soviet Union	475
United States	1780

LD_{50} (oral, mouse) 4 – 8 g/kg [67]
LD_{50} (oral, rabbit) 5.3 g/kg [67]
LD_{50} (intraperitoneal, mouse) 1.3 g/kg [67]
LD_{50}(dermal, rabbit) 20 g/kg [71]
Nonteratogenic at 39 or 78 mg per chicken egg [67]
Nonmutagenic in the *Salmonella*/microsome (Ames) test [67]
Nononcogenic on skin of mice, three times a week for 1 year [67]
Moderate corneal injury on rabbit eye [67]
Environmental toxicity: LC_{50} (rainbow trout, 96 h) 5540 mg/L; LC_{50} (bluegill sunfish, 96 h) 8300 mg/L.

Minimum lethal concentration in air (LC_{50}) was 50.1 g/m^3 (21 100 ppm) for rats exposed to acetone vapor for 8 h and 44 g/m^3 (18 500 ppm) for mice exposed for 4 h Human exposure to acetone has been studied [72–77]. Eye and nasal irritation were observed at 1.2 g/m^3. Other effects are similar to those of ethanol, but the anesthetic potency is greater. Prolonged or repeated skin contact may defat the skin and can produce dermatitis. Direct contact of acetone with the eyes can produce corneal injury. Acetone is a solvent of comparatively low acute and chronic toxicity. However it does not have sufficient warning properties to prevent repeated exposures to vapors, which may have adverse effects. There have been no reports that prolonged inhalation of low vapor concentrations result in any serious chronic effects in humans.

Cases of acetone poisoning are rare [67]. In one case, a solvent mixture containing 90 % acetone and 9 % pentane was used to set a cast for a broken leg on a 10-year-old boy [78]. The boy became ill and collapsed 12 h later. After the cast was removed the boy became comatose but recovered completely in 4 days. In another case, a 42-year-old man ingested 200 mL of acetone and became comatose for 12 h [79]. Subsequently, hyperglycemia was diagnosed and attributed to acetone ingestion.

Acetone does not cause neurotoxicity, an occupational disorder caused by exposure to some higher aliphatic ketones and related compounds [80]. Acetone vapor is absorbed with 75 % efficiency by the lungs [76]. The half-life for the elimination of acetone by expired air is approximately 5 h. The metabolism of acetone may proceed through 1,2-propanediol [67], [81], [82].

11. Derivatives

11.1. Acetone Cyanohydrin

Acetone cyanohydrin, 2-hydroxy-2-methylpropanenitrile, $CH_3C(OH)(CN)CH_3$ [*75-86-5*] is an important chemical intermediate for the manufacture of methacrylates (→ Methacrylic Acid and Derivatives). Small amounts of acetone cyanohydrin are used in insecticide manufacture.

Physical Properties. Acetone cyanohydrin is a colorless liquid. The pure compound is practically odorless but usually has an odor of bitter almonds because of traces of hydrogen cyanide. It is very soluble in water and polar solvents and sparingly soluble in hydrocarbons.

M_r 85.11, *mp* −19 °C, relative density d_4^{25} 0.9267, relative vapor density (air = 1) 2.96, refractive index n_D^{25} 1.3980, flash point 73 °C.

Vapor pressure

p, kPa	5.3	3.1	1.3	1.2
t, °C	95	82	74	72

Chemical Properties. Acetone cyanohydrin exhibits the combined characteristics of a nitrile and an alcohol. Under neutral and particularly under alkaline conditions it decomposes to acetone and hydrogen cyanide. The decomposition is inhibited by the addition of small amounts of sulfuric or phosphoric acid; consequently, technical-grade material is stabilized by addition of 0.01 wt % of either acid. Reaction with concentrated sulfuric acid converts acetone cyanohydrin to methacrylamide sulfate; subsequent neutralization with ammonia yields methacrylamide [*79-39-0*]; alcoholysis yields methacrylate esters; alternatively, hydrolysis gives methacrylic acid [*79-41-4*].The yield of methacrylic acid is improved if 3 – 10 % oleum is used instead of 100 % sulfuric acid in the reaction with acetone cyanohydrin [83].

Production. Acetone cyanohydrin is manufactured by the base-catalyzed condensation of acetone with hydrogen cyanide according to the following mechanism [84]:

The reaction is reversible but formation of the cyanohydrin is quite favorable; the equilibrium constant is 28 L/mol at 20 – 25 °C [85]. The reaction usually is carried out in the liquid phase. Representative catalysts used industrially are sodium hydroxide [86], potassium hydroxide [87], potassium carbonate [88], and anion-exchange resins. A schematic flowsheet of the Rohm & Haas [89] process is shown in Figure 3. Acetone and liquid hydrogen cyanide are fed continuously to a cooled reactor along with an alkaline catalyst. The catalyst is next neutralized with sulfuric acid and the resulting salt is removed by filtration. The crude product is then distilled in a two-stage process. The overheads from the first column consist mainly of acetone and hydrogen cyanide, which are recycled to the reactor. The second column removes water overhead and leaves 98 % pure acetone cyanohydrin at the bottom. Nitto Chemical claims a two-column distillation system that delivers acetone cyanohydrin of 99.1 % purity [90]. The manufacture of acetone cyanohydrin produces no byproducts other than small amounts of sulfate salts formed during catalyst neutralization. However, the conversion of acetone cyanohydrin to methacrylate in the classical process produces a large amount of ammonium sulfate byproduct, which is usually pyrolyzed to sulfuric acid. An alternative process developed by Mitsubishi Gas Chemical recycles the HCN via formamide. In this process HCN is not directly consumed and no ammonium sulfate is formed.

Uses. By far the largest use of acetone cyanohydrin is as an intermediate in the synthesis of methyl methacrylate [*80-62-6*], methacrylic acid, and higher methacrylate esters. A small amount is converted to methacrylamide. The estimated amount of acetone used in the manufacture of methacrylate esters in 1995 in the United States was 500×10^3 t (Table 7). Based on this estimate, the quantity of acetone cyanohydrin produced as an intermediate was approximately 714×10^3 t.

Certain esters of acetone cyanohydrin, such as 2-chloroethyl-α-cyanoisopropylsulfite [91] and α-cyanoisopropyl-2,6-dichlorobenzoate [92] have strong fungicidal, herbicidal, and insecticidal properties. Nitrilurethanes made from acetone cyanohydrin and substituted phenylisocyanates are intermediates for 4-iminooxazolidin-2-ones, which are plant growth inhibitors [93].

Transportation and Toxicology. Most acetone cyanohydrin is consumed on site for the manufacture of methacrylates. Because of its high toxicity, acetone cyanohydrin is classified

Figure 3. Rohm and Haas acetone cyanohydrin process [89]
a) Reactor; b) Cooling; c) Filter press; d) Concentrator; e) Concentrator; f) Condenser; g) Vacuum jet; h) Pump for acetone and HCN recycle

as a poison B and all shipping containers must carry a "poison inhalation hazard" label [57]. Transport aboard a passenger-carrying or cargo aircraft is forbidden [58]. Acetone cyanohydrin has the following toxicologic properties [94]: LD_{50} (oral, rat) 18.6 mg/kg; LD_{50} (oral, rabbit) 14 mg/kg; LD_{50} (dermal, rabbit) 17 mg/kg; LD_{50} (dermal, guinea pig) 150 mg/kg; aquatic toxicity rating (TLm96) 10 to 1 ppm. Threshold limit values have been established as cyanide: TLV-STEL, 4.7 ppm ceiling limit (5 mg/m^3) [68].

11.2. Diacetone Alcohol

Diacetone alcohol, 4-hydroxy-4-methyl-2-pentanone [*123-42-2*]

is a dimer of acetone that is used as a solvent and as an intermediate for the manufacture of mesityl oxide, methyl isobutyl ketone, and hexylene glycol.

Physical Properties. Diacetone alcohol is a colorless liquid of mild odor. It is miscible with water and polar solvents and is an excellent solvent for cellulose acetate and various oils and resins. M_r 116.16, *mp* −47 °C, relative density, d_4^{20} 0.9387, refractive index n_D^{20} 1.4235, heat of vaporization at the boiling point at 101.3 kPa 357.1 kJ/kg, specific heat capacity (20 °C) 18.84 kJ kg^{-1} K^{-1}, thermal expansion coefficient (20 °C) 0.00099 K^{-1}, viscosity at 20 °C 2.9 mPa · s, surface tension (20 °C) 31.0 mN/m, dielectric constant (25 °C) 18.2, heat of combustion 3544.5 kJ/mol, flash point 58 °C, lower explosion limit in air 2.6 vol %, auto ignition temperature 624 °C.

Vapor pressure

p, kPa	101.3	1.7	0.108
t, °C	168.1	61.7	20.0

Azeotropic mixture with water: *bp* 98.8 °C/101.3 kPa, 12.7 wt % diacetone alcohol.

Chemical Properties. Diacetone alcohol dehydrates readily in the presence of acids to form mesityl oxide. Catalytic hydrogenation [95] yields hexylene glycol. In the presence of bases, diacetone alcohol reverts to acetone. The reaction is first order in diacetone alcohol and first order in base. The dissociation is accompanied by volume increase; consequently, the reaction is inhibited by pressure [96]. The second-order rate constant is 7.33×10^{-4} L mol^{-1} s^{-1} at 101.3 kPa and decreases to 2.38×10^{-4} L mol^{-1} s^{-1} at 4.05×10^5 kPa. In neutral aqueous solution, dissociation to acetone is very slow at room temperature; it reaches approximately 0.1 % in 1 year.

Diacetone alcohol may be acylated by acetic anhydride under mild conditions to form diacetone alcohol acetate [*1637-25-8*], 4-methyl-4-acetyloxy-2-pentanone, which is claimed as an octane-improving gasoline additive [97]. Con-

densation with urea in the presence of sulfuric acid yields diacetone-monourea, 3,4-dihydro-4,4,6-trimethyl-2(1*H*)-pyrimidone [*4628-47-1*] [98], [99].

The compound is claimed to improve the egg-laying capacity of hens [98].

Production. Diacetone alcohol is manufactured by self-condensation of acetone in the presence of a basic catalyst. The reaction is exothermic by 14.65 kJ/mol and is easily reversible. The equilibrium concentration of diacetone alcohol is 23.1 wt % at 0 °C and decreases with increasing temperature [100]. Kinetic considerations dictate, however, a higher temperature for the manufacture of diacetone alcohol. An optimum temperature range is 10 – 20 °C.

The self-condensation of acetone is carried out in continuous-flow reactors containing a solid alkaline catalyst, such as barium hydroxide or calcium hydroxide [101], [102]. Anion-exchange resins have been investigated [103], [104], but are not believed to be used commercially. Catalyst performance deteriorates with time, but may last up to 1 year. A patent [105] describes how addition of small amounts of methanol, ethanol, or 2-propanol to the reaction mixture retards catalyst deterioration. The selectivity for diacetone alcohol is 90 – 95 %. Mesityl oxide and higher condensates, such as triacetone alcohol, are the main products. The acetone solution of the crude product is neutralized, e.g., with phosphoric acid [106], prior to concentration under reduced pressure. The recovered acetone is recycled to the condensation reactor and the acidity adjusted by subsequent addition of a base, such as triethylamine. After such treatment, diacetone alcohol of 99.68 % purity was obtained by vacuum distillation [106].

Uses. Diacetone alcohol is an excellent solvent for many natural and synthetic resins. It is used in the coatings industry, especially for hot lacquers, and is also used as a solvent for nitrocellulose, cellulose acetate, and epoxy resins. However, its use has diminished because it is not exempt from restrictions under Rule 66 and related federal regulations [52]. Therefore, US sales have declined more than 50 % since 1978, reaching 10 000 t/a for the past several years and are expected to remain flat. A large portion of diacetone alcohol is used as an intermediate for the manufacture of mesityl oxide, methyl isobutyl ketone, and hexylene glycol.

Transportation and Toxicology. Diacetone alcohol has a flash point of 58 °C, and all transport containers must carry a "flammable liquid" label. Threshold limit values (TLV) for diacetone alcohol vapor at the workplace are: 50 ppm, 240 mg/m^3 (TLV-TWA) [69]; MAK is 50 mL/m^3, 240 mg/m^3. These limits also apply to the other major industrial countries [71]. The toxicologic properties of diacetone alcohol are as follows [107]: LD_{50} (oral, rat) 4 g/kg; LD_{50} (intraperitoneal, mouse) 933 mg/kg; LD_{50} (dermal, rabbit) 13.5 g/kg; aquatic toxicity rating (TLm96) 1000 – 100 ppm.

11.3. Miscellaneous Derivatives

Acetone is used in the production of methyl amyl ketone (MAK, 2-heptanone). MAK is produced by the condensation of *n*-butyraldehyde and acetone. In 1995, US consumption of acetone for MAK was approximately 12×10^3 t, producing ca. 17.5×10^3 t of MAK. Eastman Chemical is the sole US producer. Acetone is also used to produce methyl isoamyl ketone (MIAK) by condensation of acetone with isobutyraldehyde. Eastman Chemical is the sole US producer of MIAK, which is primarily used in lacquers and surface coatings. Other minor uses of acetone include the manufacture of DuPont triazine herbicide Bladex [$(3.5 – 3.6) \times 10^3$ t/a]; Ethoxyquin, a Monsanto antioxidant (2.7×10^3 t/a), as a raw material in the production of hexafluoroacetone, methylbutynol, and pseudoionone; and as an auxiliary blowing agent for the production of flexible polyurethane foam.

1. Introduction

Acetylene [*74-86-2*] is the simplest hydrocarbon with a triple bond. In the days before oil gained widespread acceptance as the main feedstock of chemical industry, acetylene was the predominant building block of industrial organic chemistry. The calcium carbide process was the sole route for acetylene production until 1940, when thermal cracking processes using methane and other hydrocarbons were introduced. At first, these processes used an electric arc; then,

in the 1950s, partial oxidation and regenerative processes were developed.

However, along with the expansion of the petroleum industry there was a changeover from coal chemistry to petrochemistry, in the 1940s in the United States and in the 1950s in Europe. As a consequence, acetylene lost its competitive position to the much cheaper and more readily available naphtha-derived ethylene and other olefins. This competition between acetylene and ethylene as feedstocks for chemical industry has been much discussed in the 1960s and 1970s [1, 2]. The few hopes, such as BASF's contribution to the submerged flame process, Hoechst's crude oil cracking (HTP), or Hüls' plasma process, have not halted the clear trend toward ethylene as a basic chemical. With the first oil price explosion in 1973, the development of crude cracking processes suffered a setback, and the new processes, such as the Kureha/Union Carbide process, DOW's PCC process (PCC = partial combustion cracking), or the Kureha/Chiyoda/Union Carbide ACR process (ACR = advanced cracking reactor), raise little hope for a comeback of acetylene chemistry. Acetylene production peaked in the United States at 480000 t in the 1960s, and in Germany at 350000 t in the early 1970s [3]. Since then, acetylene production has decreased steadily. In both countries the losses were principally in carbide-derived acetylene; in fact, Germany has produced acetylene for chemical purposes almost exclusively from natural gas and petrochemical sources since 1975.

All acetylene processes, including carbide processes, are high-temperature processes, requiring a large amount of energy. They differ essentially only in the manner in which the necessary energy is generated and transferred. They can be classified into three groups: partial combustion processes, electrothermic processes, and processes using heat carriers. Finally, the use of byproduct acetylene from olefin plants is economically viable in many cases. For each group of acetylene processes several variants have been developed using various feedstocks and techniques. Today, only three processes remain for the commercial production of acetylene: the *calcium carbide route*, in which the carbide is produced electrically, the *arc process*, and the *partial oxidation of natural gas*. Other once popular processes have become uneconomical as the price of naphtha has increased.

Some processes were shelved in the experimental or pilot-plant stage as the importance of acetylene declined. However, other new processes involving the use of coal, sulfur-containing crude oil, or residues as feedstocks for acetylene production are in the pilot-plant stage.

However, the position of acetylene in chemical industry may improve because of the variety of valuable products to which acetylene can be converted with known technology and high yields.

2. Physical Properties

Due to the carbon–carbon triple bond and the high positive energy of formation, acetylene is an unstable, highly reactive unsaturated hydrocarbon. The C – C triple bond and C – H σ bond lengths are 0.1205 and 0.1059 nm, respectively. For the electronic structure of acetylene and a molecular orbital description, see [4]. The acidity of acetylene ($pK_a = 25$) permits the formation of acetylides (see Section 3.2). For comparison the pK_a value of ethylene is 44 and that of acetone 20.

Figure 1. Vapor pressure of acetylene [5, 6]

Under normal conditions acetylene is a colorless, nontoxic but narcotic gas; it is slightly lighter than air. The main physical properties are listed in Table 1. The critical temperature and pressure are 308.32 K and 6.139 MPa. The triple point at 128.3 kPa is 192.4 K. The vapor pressure curve for acetylene is shown in Figure 1. The formation of acetylene is strongly endothermic (ΔH_f = + 227.5 kJ/mol at 298.15 K).

Table 1. Physical properties of acetylene [5 – 8]

Molecular mass	26.0379
Critical temperature	308.32 K (35.17 °C)
Critical pressure	6.139 MPa
Critical volume	0.113 m^3/kmol
Triple point	192.4 K (− 80.75 °C)
Triple point pressure	128.3 kPa
Normal sublimation point and normal boiling point	189.15 K (− 84.0 °C)
Crystal transition point	133.0 K (− 140.15 °C)
Enthalpy of transition	2.54 kJ/mol
Density	760.2 kg/m^3 (131 K) 764.3 kg/m^3 (141 K)
Density (liquid C_2H_2)	465.2 kg/m^3 (273.15 K)
Density (gaseous C_2H_2 at 1 bar)	1.095 kg/m^3 (288.15 K)
Molecular volume (0 °C, 1.013 bar)	22.223 m^3/kmol
Enthalpy of vaporization(calculated)	10.65 kJ/mol (273.15 K)
Enthalpy of sublimation	21.168 kJ/mol (5.55 K)
Enthalpy of formation	227.5 ± 1.0 kJ/mol (298.15 K)
Gibbs free energy of formation	209.2 ± 1.0 kJ/mol (298.15 K)
Entropy of formation	200.8 J mol^{-1} K^{-1} (298.15 K)
Enthalpy of combustion	−1255.6 kJ/mol (298.15 K)
Higher heating value	50 400 kJ/kg
Lower heating value	48 700 kJ/kg
Vapor pressure	2.6633 MPa (273.15 K)
Thermal conductivity	0.0184 W m^{-1} K^{-1} (0 °C, 1.013 bar)
Heat capacity (ideal gas state)	43.990 J mol^{-1} K^{-1} (298.15 K)

Self-decomposition can be initiated when certain pressure limits above atmospheric pressure are exceeded (for details see Section 5.1).

The crystalline structure of solid acetylene changes at − 140.15 °C from a cubic to an orthorhombic phase. The heat of reaction for this phase change is 2.54 kJ/mol [7]; two different values for the enthalpy of fusion are reported in the literature [5, 6]. Figure 2 shows the density of liquid and gaseous acetylene.

Details about flame properties, decomposition, and safety measures are given in Chapter 5.

Solubility coefficients of acetylene in organic solvents are listed in Table 2 [9]. Further solubility data are available as Bunsen absorption coefficients α (20 °C, m^3 (STP) m^{-3} atm^{-1}), as solubilities (g/kg of solvent), and for different pressures (see [10]). The solubilities of acetylene at infinite dilution are shown in Figure 3 for water, methanol, DMF, and *N*-methyl-2-pyrrolidone (NMP) [*872-50-4*]. Figure 4 shows the solubility of acetylene in acetone for various partial pressures and temperatures. While at 20 °C and 1.013 bar 27.9 g (51.0 g) acetylene can be dissolved in 1 kg acetone (DMF) at 20.26 bar 689.0 g (628.0 g) can be dissolved in the same amount of solvent [131]. The heat of solution depends on the concentration of acetylene in the solvent: dissolving 0.5 kg of acetylene in 1 kg of solvent generates 293 kJ for acetone and 335 kJ for DMF. For details on the influence of water, of partial pressure, and deviations from Henry's law, see [9, 10]. Only at temperatures above 25 °C and pressures < ca. 10 bar the solubility of acetylene in acetone follows Henry's law. At higher pressures the solubility increases more rapidly than predicted by Henry's law [132]. The temperature dependence of the solubility of acetylene in DMF at infinite dilution is compared with those of ethylene and ethane in Figure 5 (see also [9, 11] for selectivities).

Figure 2. Density of acetylene vapor (at 1.013 bar) and liquid

Figure 3. Solubility of acetylene in various solvents at infinite dilution

Figure 4. Solubility of acetylene in acetone [9]

The solubility of acetylene in water at 25 °C is 0.042 mol L^{-1} bar^{-1}. Under pressure of acetylene (e.g., > 0.5 MPa at 0 °C) and at temperatures between 268 and 283 K, waxy hydrates of the composition $C_2H_2 \cdot (H_2O)_{\sim 5.8}$ are formed [9, 10]. The hydrates can block equipment; shock waves may initiate self-decomposition.

Liquid oxygen dissolves only traces of acetylene (5.5 ppm at 90 K [12]); the solubilities of ethylene and ethane in oxygen are much higher (factor of 350 and 2280, respectively). The prepurification of the process air in air separation plants with molecular sieves removes acetylene to < 1 ppb provided there is no breakthrough of carbon dioxide. This fact guarantees a safe operation of the downstream equipment [13].

Figure 5. Solubility of C_2 hydrocarbons in DMF at infinite dilution

Typical adsorption isotherms of acetylene are shown in Figure 6 for molecular sieves, activated carbon and silica gel at 25 °C [14]; additional information for activated carbon is summarized in [15].

Figure 6. Adsorption isotherms for acetylene on 4A and 5A molecular sieves, activated carbon, and silica gel at 25 °C [14]

Table 2. Solubility coefficients of C_2H_2 in various solvents (in mol kg^{-1} bar^{-1}) [9]

Solvent	C_2H_2 pressure, bar	− 20 °C	25 °C
Methanol	0.98	1.979	0.569
Ethanol	0.98	0.851	0.318
n-Butanol	0.245 – 0.657		0.237
1,2-Dichloroethane	0.4–1.05	0.569	0.218
Carbon tetrachloride	0.98	0.164	0.075
n-Hexane	6.90	0.523	0.264
n-Octane	0.196 – 14.71	0.205	0.146 (0° C)
Benzene	0.98		0.225
Toluene	0.98	0.619	0.214
Xylene (tech.)	0.98	0.528	0.189
4-Methyl-1,3-dioxolan-2-one (propylene carbonate)	0.98	1.137	0.350
Tri-*n*-butylphosphate	0–0.4	2.366	0.614
Methyl acetate	0.98	2.912	0.878
Triethylene glycol	0.98		0.205

Dimethyl sulfoxide	0.98		1.001
Ammonia	0.98	7.052	2.229

3. Chemical Properties

Because of its strongly unsaturated character and high positive free energy of formation, acetylene reacts readily with many elements and compounds. As a result acetylene is used as raw material for a great variety of substances. Important are addition reactions, hydrogen replacements, polymerization, and cyclization.

Acetylene is more susceptible to nucleophilic attack than, for instance, ethylene. In addition, the polarized C-H bond makes acetylene acidic (pK_a = 25) [16]. Because of this acidity, acetylene is very soluble in basic solvents [17, 18], forming hydrogen bonds with them [19]. Therefore, the vapor pressures of such solutions cannot be described by Raoult's law [20].

The development of the acetylene pressure reactions by W. Reppe (1892 – 1969), BASF Ludwigshafen (Germany) [21 – 23] began modern acetylene chemistry. The most interesting groups of reactions are vinylation, ethynylation, carbonylation, and cyclic and linear polymerization.

3.1. Industrially Important Reactions

Vinylation Reactions and Products [24]. Vinylation is the addition of compounds with a mobile hydrogen atom, such as water, alcohols, thiols, amines, and organic and inorganic acids, to acetylene to form vinyl compounds chiefly used for polymerization.

The two types of vinylation reactions are *heterovinylation* and the less usual *C vinylation.* In the former, the hydrogen atom originates from the heteroatoms O, S, and N, whereas C vinylation occurs when the mobile hydrogen atom is directly bound to a carbon atom. Examples of C vinylation are dimerization and trimerization of acetylene, the synthesis of acrylonitrile from acetylene and hydrogen cyanide, and the addition of acetylene to unsaturated hydrocarbons with activated hydrogen atoms, such as cyclopentadiene, indene, fluorene, and anthracene.

The first industrial vinylation products were acetaldehyde, vinyl chloride, and vinyl acetate. Many other products followed.

Some examples of industrial vinylation processes are given below:

Acetaldehyde [*75-07-0*] (→ Acetaldehyde):

$$HC{\equiv}CH + H_2O \rightarrow CH_3CHO$$

Catalyst: acidic solutions of mercury salts, such as $HgSO_4$ in H_2SO_4 . Liquid-phase reaction at 92 °C.

Vinyl chloride [*75-01-4*] (→ Chlorinated Hydrocarbons):

$$HC{\equiv}CH + HCl \rightarrow CH_2 = CHCl$$

Catalyst: $HgCl_2$ on coal. Gas-phase reaction at 150 – 180 °C.

Vinyl acetate [*108-05-04*] (→ Vinyl Esters):

$$HC{\equiv}CH + CH_3COOH \rightarrow CH_2 = CHOOCCH_3$$

Catalyst: cadmium, zinc, or mercury salts on coal. Gas-phase reaction at 180 – 200 °C.

Vinyl ethers (→ Vinyl Ethers), conjectured reaction steps:

$$ROH + KOH \xrightarrow{-H_2O} ROK \xrightarrow{C_2H_2} RO-CH=CHK$$
$$RO-CH=CHK + ROH \rightarrow RO-CH=CH_2 + ROK$$

where R is an alkyl group. Reaction temperature of 120 – 150 °C; pressure high enough to avoid boiling the alcohol used, e.g., 2 MPa with methanol to produce methyl vinyl ether (acetylene pressure reaction).

Vinyl phenyl ether [*766-94-9*], vinylation with KOH catalyst:

Vinyl sulfides, KOH catalyst:

$$HC{\equiv}CH + RSH \rightarrow CH_2 = CH-S-R$$

Vinyl esters of higher carboxylic acids:

$$HC{\equiv}CH + R-COOH \rightarrow RCOO-CH = CH_2$$

Catalyst: zinc or cadmium salts. Liquid-phase reaction.

Vinyl amines, vinylation with zinc or cadmium compounds as catalyst:

$$R^1R^2NH + HC{\equiv}CH \rightarrow R^1R^2N-CH = CH_2$$

where R^1 and R^2 are alkyl groups.

N-Vinylcarbazole [*1484-13-5*], vinylation of carbazole in a solvent, e.g., *N*-methylpyrrolidone, at 180 °C.

Vinylation of ammonia, complex Co and Ni salts as catalysts, reaction temperature of 95 °C:

Vinylation of acid amides, potassium salt of the amide as catalyst:

$$HC{\equiv}CH + RCO-NH_2 \rightarrow RCO-NH-CH = CH_2$$

N-Vinyl-2-pyrrolidone [*88-12-0*], vinylation of 2-pyrrolidone with the potassium salt of the pyrrolidone as catalyst.

Acrylonitrile [*107-13-1*], C-vinylation of HCN in aqueous hydrochloric acid with CuCl and NH_4Cl catalyst:

$$HC{\equiv}CH + HCN \rightarrow H_2C = CH-CN$$

Ethynylation Reactions and Products [25]. Ethynylation is the addition of carbonyl compounds to acetylene with the triple bond remaining intact. Reppe found that heavy metal acetylides (see Section 3.2), especially the copper(I) acetylide of composition $Cu_2C_2 \cdot 2\,H_2O \cdot 2\,C_2H_2$, are suitable catalysts for the reaction of aldehydes with acetylene. Alkaline catalysts are more effective than copper acetylide for the ethynylation of ketones. The generalized reaction scheme for ethynylation is:

$$HC{\equiv}CH + RCOR' \rightarrow HC{\equiv}C-C(OH)RR'$$

where R and R′ are alkyl groups or H.

The most important products from ethynylation are propargyl alcohol and butynediol.

Propargyl alcohol, 2-propyn-1-ol [*107-19-7*] (→ Alcohols, Aliphatic):

$$CH{\equiv}CH + HCHO \rightarrow HC{\equiv}CCH_2OH$$

Catalyst: $Cu_2C_2 \cdot 2\,H_2O \cdot 2\,C_2H_2$.

Butynediol, 2-butyne-1,4-diol [*110-65-6*] (→ Butanediols, Butenediol, and Butynediol):

$$HC{\equiv}CH + 2\ HCHO \rightarrow HOCH_2C{\equiv}CCH_2OH$$

Catalyst: $Cu_2C_2 \cdot 2\,H_2O \cdot 2\,C_2H_2$.

Other examples of ethynylation are the reactions of aminoalkanol and secondary amines with acetylene:

Carbonylation Reactions and Products [26]. Carbonylation is the reaction of acetylene and carbon monoxide with a compound having a mobile hydrogen atom, such as water, alcohols, thiols, or amines. These reactions are catalyzed by metal carbonyls, e.g., nickel carbonyl, $Ni(CO)_4$ [*13463-39-3*]. Instead of metal carbonyls, the halides of metals that can form carbonyls can also be used.

Acrylic acid [*79-10-7*] (→ Acrylic Acid and Derivatives):

$$HC{\equiv}CH + CO + H_2O \rightarrow CH_2 = CH{-}COOH$$

The reaction of acetylene with water or alcohols and carbon monoxide using $Ni(CO)_4$ catalyst was first reported by W. Reppe [26]. If water is replaced by thiols, amines, or carboxylic acids, then thioesters of acrylic acid, acrylic amides, or carboxylic acid anhydrides are obtained.

Ethyl acrylate [*140-88-5*] (→ Acrylic Acid and Derivatives):

Catalyst: nickel salts. Reaction temperature: 30 – 50 °C. The process starts with the stoichiometric reaction (1); afterwards, most of the acrylate is formed by the catalytic reaction (2). The nickel chloride formed in the stoichiometric reaction (1) is recovered and recycled for carbonyl synthesis.

Hydroquinone [*123-31-9*] is formed in a suitable solvent, e.g., dioxane, at 170 °C and 70 MPa [27]. The catalyst is $Fe(CO)_5$:

Hydroquinone is formed at 0 – 100 °C and 5 – 35 MPa if a ruthenium carbonyl compound is used as catalyst [28]:

Bifurandiones: The reaction of acetylene and CO in the presence of octacarbonyldicobalt, $(CO)_3Co - (CO)_2 - Co(CO)_3$ [*10210-68-1*], forms a cis–trans mixture of bifurandione. The reaction is carried out under pressure (20 – 100 MPa) at temperatures of about 100 °C [29]:

New aspects of such CO insertion reactions have been reported [30].

Cyclization and Polymerization of Acetylene. In the presence of suitable catalysts, acetylene can react with itself to form cyclic and linear polymers.

Cyclization was first observed by Berthelot, who polymerized acetylene to a mixture of aromatic compounds including benzene and naphthalene. In 1940, Reppe synthesized 1,3,5,7-cyclooctatetraene [*629-20-9*] with a 70 % yield at an only slightly elevated pressure:

Reaction temperature of 65 – 115 °C, pressure of 1.5 – 2.5 MPa, $Ni(CN)_2$ catalyst.

The reaction is carried out in anhydrous tetrahydrofuran. The byproducts are mostly benzene (about 15 %), chain oligomers of acetylene of the empirical formulas $C_{10}H_{10}$ and $C_{12}H_{12}$, and a black insoluble mass, called niprene after the nickel catalyst.

If dicarbonylbis(triphenylphosphine)nickel [*13007-90-4*], $Ni(CO)_2[(C_6H_5)_3P]_2$, is used as catalyst, the cyclization products are benzene (88 % yield) and styrene (12 % yield). The reaction is carried out in benzene at 65 – 75 °C and 1.5 MPa [31, 32].

Linear polymerization of acetylene occurs in the presence of a copper (I) salt such as CuCl in hydrochloric acid. Reaction products are vinylacetylene, divinylacetylene, etc. [33]:

$$HC{\equiv}CH + HC{\equiv}CH \rightarrow H_2C = CH{-}C{\equiv}CH$$

A particular polymerization product, known as *cuprene*, is formed when acetylene is heated to 225 °C in contact with copper sponge. Cuprene is chemically inert, corklike in texture, and yellow to dark brown.

Polyacetylene [34, 35] is formed with Ziegler–Natta catalysts, e.g., a mixture of trieth-

ylaluminum, $Al(C_2H_5)_3$, and titanium tetrabutoxide, $Ti(n\text{-}OC_4H_9)_4$, at 10^{-2} to 1 MPa:

Polymerization can be carried out in an auxiliary inert liquid, such as an aliphatic oil or petroleum ether. The monomer can also be copolymerized in the gas phase.

Polyacetylene is a low-density sponge-like material consisting of fibrils with diameters of 20 – 50 nm. The ratio *cis*- to *trans*-polyacetylene depends on the reaction temperature.

Polyacetylene doped with electron acceptors (I_2, AsF_5), electron donors (Na, K), or protonic dopants ($HClO_4$, H_2SO_4) is highly conductive and has the properties of a one-dimensional metal [35].

3.2. Other Reactions; Derivatives

Metal Acetylides [36]. The hydrogen atoms of the acetylene molecule can be replaced by metal atoms (M) to yield metal acetylides. Alkali and alkaline-earth acetylides can be prepared via the metal amide in anhydrous liquid ammonia:

$$C_2H_2 + MNH_2 \rightarrow MC_2H + NH_3$$

The direct reaction of the acetylene with a molten metal, such as sodium, or with a finely divided metal in an inert solvent, such as xylene, tetrahydrofuran, or dioxane, at a temperature of about 40 °C, is also possible:

$$2\ M + C_2H_2 \rightarrow M_2C_2 + H_2$$

The very explosive copper acetylides, e.g., $Cu_2C_2 \cdot H_2O$, can be obtained by reaction of copper(I) salts with acetylene in liquid ammonia or by reaction of copper(II) salts with acetylene in basic solution in the presence of a reducing agent such as hydroxylamine. Copper acetylides can also form from copper oxides and other copper salts. For this reason copper plumbing should be avoided in acetylene systems.

Silver, gold, and mercury acetylides, which can be prepared in a similar manner, are also explosive.

In sharp contrast to the highly explosive $Cu_2C_2 \cdot H_2O$, the catalyst used for the synthesis of butynediol, $Cu_2C_2 \cdot 2\ H_2O \cdot 2\ C_2H_2$, is not as sensitive to shock or ignition.

Halogenation. The addition of chlorine to acetylene in the presence of $FeCl_3$ yields 1,1,2,2-tetrachloroethane [*79-34-5*], an intermediate in the production of the solvents 1,2-dichloroethylene [*540-59-0*], trichloroethylene [*79-01-6*], and perchloroethylene [*127-18-4*].

Bromine and iodine can also be added to acetylene. The addition of iodine to acetylene stops with formation of 1,2-diiodoethylene.

Hydrogenation. Acetylene can be hydrogenated, partly or completely, in the presence of Pt, Pd, or Ni catalysts, giving ethylene or ethane.

Organic Silicon Compounds [37, 38]. The addition of silanes, such as $HSiCl_3$, can be carried out in the liquid phase using platinum or platinum compounds as catalysts:

$$HC{\equiv}CH + HSiCl_3 \rightarrow CH_2 = CH{-}SiCl_3$$

Oxidation. At ambient temperature acetylene is not attacked by oxygen; however, it can form explosive mixtures with air or oxygen (see Chap. 5). The explosions are initiated by heat or ignition. With oxidizing agents such as ozone or chromic acid, acetylene gives formic acid, carbon dioxide, and other oxidation products. The reaction of acetylene with dilute ozone yields glyoxal.

Hydrates. At temperatures below ca. 15 °C, under pressure, hydrates of the composition $C_2H_2 \cdot 6\ H_2O$ are formed (see Section 2).

Chloroacetylenes [39].

Monochloroacetylene, HC≡CCl, M_r 60.49, *bp* −32 to −30 °C, a gas with nauseating odor that irritates the mucous membranes, is obtained by reaction of 1,2-dichloroethylene with alcoholic NaOH in the presence of $Hg(CN)_2$. It ignites in the presence of traces of oxygen. In air it explodes violently. Chloroacetylene is very poisonous.

Dichloroacetylene, ClC≡CCl, M_r 94.93, *mp* − 66 to − 64.2 °C, a colorless oil of unpleasant odor, explodes in the presence of air or on heating. It is obtained from acetylene in strongly alkaline potassium hypochlorite solution [40] or by reaction of trichloroethylene vapor with caustic alkali.

4. Production

4.1. Thermodynamic and Kinetic Aspects

The production of acetylene from hydrocarbons, e.g.,

$$2\ CH_4 \rightleftharpoons C_2H_2 + 3\ H_2 \quad \Delta H\ (298\ K) = 376.4\ kJ/mol$$

requires very high temperatures and very short reaction times. The main reasons for the extreme conditions are the temperature dependence of the thermodynamic properties (molar enthalpy of formation, ΔH_f, and molar free energy of formation, ΔG_f) of the hydrocarbons; the position of the chemical equilibria under the reaction conditions; and the kinetics of the reaction.

Table 3. Standard molar enthalpies of formation and Gibbs free energy of formation at 298 K

	ΔH_f (kJ/mol)	ΔG_f (kJ/mol)
C (s)	0	0
H_2 (g)	0	0
CH_4 (g)	− 74.81	− 50.82
C_2H_2 (g)	+226.90	+209.30
C_2H_4 (g)	+ 52.30	+ 68.15
C_2H_6 (g)	− 84.64	− 32.90
C_3H_6 (g)	+ 20.43	+ 62.75
C_3H_8 (g)	−103.90	− 23.48
n-C_4H_{10} (g)	−126.11	− 17.10

Thermodynamic data relevant to the hydrocarbon–acetylene system are shown in Table 3 and Figure 7. These data show clearly that at normal temperatures acetylene is highly unstable compared to the other hydrocarbons. However, Figure 7 also shows that the free energy of acetylene decreases as temperature increases, whereas the free energies of the other hydrocarbons increase. Above about 1230 °C, acetylene is more stable than the other hydrocarbons. The temperature at which the acetylene line intersects an other line in Figure 7 is higher the shorter the chain length of the hydrocarbons. Acetylene production from methane requires higher reaction temperatures than production from heavier hydrocarbons.

Figure 7. Gibbs free energy of formation per carbon atom of several hydrocarbons as a function of temperature

The equilibrium curve for the methane reaction as a function of temperature (Fig. 8) shows that acetylene formation only becomes apparent above 1000 K (730 °C). Therefore, a very large energy input, applied at high temperature, is required.

Figure 8. Equilibrium curve for the methane cracking reaction, $2\ CH_4 \rightleftharpoons C_2H_2 + 3\ H_2$

However, even at these high temperatures acetylene is still less stable than its component elements, carbon und hydrogen (see Fig. 7). In

fact, the large difference in free energy between acetylene and its component elements favors the decomposition of acetylene to carbon and hydrogen up to temperatures of about 4200 K.

$$C_2H_2 \rightarrow 2\ C(s) + H_2\ (g) - \Delta G_f\ (298\ K) = -209.3\ kJ/mol$$

Thus cracking and recombination of the hydrocarbons and decomposition of acetylene compete. To achieve reasonable acetylene yields and to avoid the thermodynamically favorable decomposition into the elements, rapid quenching of acetylene produced in the cracking reaction is necessary. In practice, the residence time at high temperature is between 0.1 and 10 ms.

Higher temperatures also increase the rate of conversion of acetylene to byproducts. Again, the residence time must be sufficiently short to prevent this.

In the case of cracking by partial oxidation, the combustion reaction of the hydrocarbon supplies the energy necessary for the production of acetylene from the other part of the hydrocarbon feed:

$$CH_4 + O_2 \rightarrow CO + H_2 + H_2O\ \Delta H\ (298\ K) = -277.53\ kJ/mol$$

$$CO + H_2O \rightarrow CO_2 + H_2\ \Delta H\ (298\ K) = -41.19\ kJ/mol$$

From these reaction enthalpies, the amount of oxygen needed to produce the high reaction temperature can be calculated. Therefore, in addition to the short residence time, the correct methane : oxygen ratio, which also determines the reaction temperature, is essential to obtain good acetylene yields.

4.2. Partial Combustion Processes

In this group of processes, part of the feed is burnt to reach the reaction temperature and supply the heat of reaction. The necessary energy is produced where it is needed. Almost all carbon-containing raw materials can be used as feedstocks: methane, ethane, natural gas liquids (NGL), liquefied petroleum gas (LPG), naphtha, vacuum gas oil, residues, and even coal or coke. Natural gas is especially suitable because it is available in many parts of the world. Only under the conditions of acetylene synthesis can methane be transformed into another hydrocarbon in a single process step, and this is the essential reason for using the thermodynamically unfavorable acetylene synthesis.

The partial combustion processes for light hydrocarbons, from methane to naphtha, all follow similar schemes. The feed and a certain amount of oxygen are preheated separately and introduced into a burner. There they pass through a mixing zone and a burner block into the reaction zone, where they are ignited. On leaving the reaction zone the product mixture is cooled rapidly, either by water or oil. Cooling by water is easier, and more common, but it is thermally less efficient than cooling by oil. Alternatively, the gases can be cooled with light hydrocarbon liquids, which leads to additional acetylene and ethylene formation between 1500 and 800 °C. These processes are usually called *two-step processes*.

Burner design is very important for all partial combustion processes. The residence time of the gas in the reaction zone must be very short, on the order of a few milliseconds, and it should be as uniform as possible for all parts of the gas. Flow velocity within the reaction zone is fixed within narrow limits by the requirements of high yield and the avoidance of preignition, flame separation from the burner block, and coke depositions. A survey of the processes operating according to these principles is given in [7, 41]. Only the BASF process is described here in detail, because it is the most widely used process for the partial combustion of natural gas.

The *submerged flame process*, SFP, was developed by BASF with the aim of producing acetylene from crude oil or its heavy fractions, and thus to be independent of the more expensive refined oil products used in olefin chemistry. One unit of this kind was built in Italy, but it became uneconomic and was shut down after a year of operation [42]. Nevertheless, the process is described in some detail below because of its simple cracking section, because of the simultaneous formation of acetylene and ethylene, and because of its high thermal efficiency and its high degree of carbon conversion (perhaps of even greater importance in the future).

The *partial combustion carbide process*, also developed by BASF, uses coke, oxygen, and lime as feed. It was developed in the 1950s to

reestablish the competitive position of carbide in the face of the new acetylene processes on a petrochemical–natural gas basis. Some attention is given here to the basics of this process, although it has never gone beyond the pilot-plant stage. When petrochemical feedstocks become scarce, this process may have a place in a future coalbased chemistry because it has a higher degree of carbon conversion and a higher thermal efficiency than the electric carbide process.

All these acetylene processes based on partial combustion yield a number of byproducts, such as hydrogen and/or carbon monoxide, which may cause problems if acetylene is the only product desired. Within a complex chemical plant, however, these may be converted to synthesis gas, pure hydrogen, and pure CO and can actually improve the economics of acetylene production.

4.2.1. BASF Process (Sachsse-Bartholome)

The BASF process for the production of acetylene from natural gas has been known since 1950 [43]. Worldwide, some 13 plants used this process in 1983, a total capacity of about 400000 t/a. All use a water quench, except the plant in Ludwigshafen (Germany) operated with an oil quench [44].

The basic idea of partial combustion involves a flame reaction on a premixed feed of hydrocarbon and oxygen. In this way the rate of hydrocarbon conversion is made independent of the gas-mixing rate, which is governed by diffusion. Only then can the residence time in the reaction zone be made much smaller than the average decay time of acetylene. The separate preheating of the reactants to the highest temperature possible before introduction into the burner reduces the consumption of oxygen and the hydrocarbon within the burner. It also causes a higher flame propagation speed and therefore a higher mass flow within the acetylene burner.

The smallest, but most important, part of a partial oxidation acetylene plant is the burner, Figure 9. Its design is nearly identical in the two process variants (i.e., oil and water quench).

At the top of the burner, the preheated reactants, (600 °C in the case of methane) must be mixed (c) so rapidly that there are no domains with a high oxygen concentration. Such domains cause preignition before the reactants are introduced into the reaction zone (g). In fact, the reaction mixture ignites after an induction time depending on the hydrocarbon used as feed and on the preheat temperature, on the order of a few tenths of a second. The maximum preheat temperature is lower for higher hydrocarbons than for methane. Backmixing of the gas between the mixing and the reaction zones is avoided by the diffuser (e), a tube which connects the mixing zone and the burner block (f). Because of its smooth surface and the small opening angle the reaction feed is decelerated gently and backmixing does not occur.

The burner block (f) consists of a water-cooled steel plate with a large number of small channels. The flow velocity through these channels is substantially higher than the flame propagation speed, so that the flame below the burner block cannot backfire into the diffuser. The lower side of the burner block has small openings between the channels through which additional oxygen is fed into the reaction mixture. At these openings small flames form and initiate the flame reaction. The strong turbulence below the burner block stabilizes the flame.

Under unfavorable conditions the flame may appear above the burner block. In this case the oxygen feed must be shut off immediately and replaced by nitrogen. This extinguishes the preignition before it can cause any damage to the equipment. Such preignitions can result from a momentary shift in the oxygen : hydrocarbon ratio or the entrainment of small particles of pyrophoric iron formed from rust in the preheaters.

As mentioned above, the hot gas leaves the reaction chamber within a few milliseconds and passes through sprays of water or oil, which cool the gas almost instantaneously, to about 80 °C in the case of water or 200 – 250 °C in the case of oil. The quench system consists of a set of nozzles that are fed by three annular tubes below the reaction chamber.

The concentrations of the major constituents of the cracked gas depend on the oxygen : hydrocarbon ratio in the feed as shown in Figure 10. As the oxygen supply is increased, the acetylene concentration increases until it passes through a smooth maximum. At the same time there is an increase in the volume of the cracked gas. Thus maximum acetylene production is attained when a little more oxygen is used than the amount

required for maximum acetylene concentration in the cracked gas. This is clear from the consumption of natural gas per ton of acetylene produced and the reduction in unconverted methane. When the oxygen : hydrocarbon ratio is too low, the reaction time is insufficient for complete conversion of oxygen, and the cracked gas contains free oxygen. Free oxygen can be tolerated only up to a certain concentration. When the oxygen : hydrocarbon ratio is too high, the increased velocity of flame propagation exceeds the flow velocity in the channels of the burner block, leading to preignitions.

Figure 10. Burner characteristics
a) Burner block; b) Reaction chamber; c) Flame front; d) Quench-medium inlet

Coke deposits in the reaction chamber have to be removed from time to time with a manual or an automatic scraper. Normally, a burner produces 25 t of acetylene per day from natural gas and 30 t per day from liquid feedstocks.

Acetylene Water Quench Process (AWP), Soot Removal (Fig. 11). After quenching with water the cracked gas leaves the burner (b) at 80 – 90 °C. A certain amount of soot is formed in the reaction chamber in spite of the very short reaction time. When natural gas is used as a feedstock, the soot is 50 kg per ton of acetylene, with LPG feedstock it is 250 kg, and with naphtha it is 350 kg. The soot is partly removed from the gas by the quench, then by washing with recirculated water in a cooling column (c), and by passing the gas through an electrofilter (d). After cooling and soot removal, the gas has a pressure slightly above atmospheric, a temperature of about 30 °C, and a soot content of about 1 mg/m^3. The water effluents from the quench system, the cooling column, and the electrofilter carry the washed-out soot. Some gas remains attached to the soot, causing it to float when the soot-containing water flows slowly through basin decanters (e). The upper soot layer, which contains 4 – 8 wt % of carbon, depending on the feedstock, is scraped off the water surface and incinerated.

Acetylene Oil Quench Process (AOP), Soot Removal (Fig. 12). In this process the cracked gas is quenched with oil sprays and leaves the burner at 200 – 250 °C. The oil absorbs the heat from the gas and then passes through waste heat boilers before returning to the quench. The sensible heat of the cracked gas represents more than 15 % of the heating value of the feedstock. The pressure of the generated steam depends on the process configuration and can reach 15 bar (1.5 MPa).

Unlike the water quench process, where the scraped coke deposits sink to the bottom of the quench chamber and are easily removed, in the oil quench the coke deposits do not settle immediately. In order to prevent plugs in the quench nozzles a mill pump (d) is installed immediately underneath the burner column.

The coke and soot content in the quench circuit is kept near 25 % by sending a fraction of the coke-containing oil to externally heated, stirred kettles (coker (e)). In the kettles the volatile matter evaporates very quickly, leading to fluidization of the coke bed. The vapor is returned to the burner column, while the soot is agglomerated. A fine-grained coke is withdrawn from the bottom of the coker.

Because of the cracking losses in the quench a certain amount of quench oil has to be added continuously to the process. This makeup oil is at least 0.15 to 0.3 t per ton of acetylene, depend-

ing on the stability of the oil used. When residual oil from steam crackers is used, it can be desirable to add up to 1 t of oil per ton of acetylene, because the excess oil is partially converted to light aromatic hydrocarbons.

The cracked gas leaving the quench is cooled in a burner column (c), where there are additional oil circuits for the production of 3-bar steam and for boiler feedwater preheat. At the top of the column a small amount of a low-boiling oil (BTX = benzene, toluene, and xylene) is added to prevent deposit-forming aromatics (mainly naphthalene) from passing downstream into other parts of the plant. The cracked gas, which has to be compressed before separation, is cooled further (g) by water. At this stage most of the BTX condenses and is separated from the water in a large decanter (f).

Table 4 shows the cracked gas compositions for the BASF acetylene oil quench process when natural gas, liquid petroleum gas (LPG), or naphtha is used as feedstock. The water quench process gives very similar compositions. The relative amounts of hydrogen and carbon monoxide formed depend on the hydrogen : carbon ratio of the feedstock used. Even when naphtha is used, almost no ethylene forms. This is because the reaction takes place above 1200 °C where the formation of ethylene is thermodynamically impossible. Only a prequench with additional naphtha or LPG produces additional acetylene and ethylene at intermediate temperatures, as in the case of two-step processes. The higher hydrocarbons require a somewhat lower reaction temperature than methane and have a less endothermic heat of reaction: oxygen consumption per ton of acetylene is lower for the higher hydrocarbons in spite of the lower preheating temperature.

Comparison of Oil Quench and Water Quench Processes. The advantage of the oil quench process is obvious: the heat recovery in the form of steam makes the overall thermal efficiency in relation to primary energy input rather high. If the thermal efficiency for the production of electricity is 33 %, over 70 % of the net heating value of the overall primary energy input is recovered in the form of products and steam. A comparison between the oil quench and water quench (see Table 6) shows that the oil quench requires a net heating value input of 300 – 330 GJ per ton of acetylene, of which 82 GJ (27 – 25 %) is lost, whereas the water quench requires a 288 GJ input, of which 113 GJ (39 %) is lost.

Acetylene Recovery. Liquid acetylene is a dangerous product, even at low temperatures. Separation of the cracked gas by cryogenic processes such as those used in olefin production is clearly ruled out. One exception to this rule is the acetylene recovery unit of the submerged flame process (Section 4.2.3) [45], in which all hydrocarbons except methane are condensed at −165 °C. Otherwise, acetylene is recovered by *selective* absorption into a solvent. This procedure is economical only when the cracked gas is compressed. The upper limit for the pressure is determined by the danger of explosions, and as a rule the partial pressure of acetylene should be kept below 1.4 bar (0.14 MPa).

The solubility of acetylene in the solvents used is between 15 and 35 m^3 (STP) per cubic meter of solvent under process conditions. The dissolved gas is recovered by depressurizing the solvent and by vapor stripping at higher temperatures. All solvents used commercially, *N*-methylpyrrolidone (NMP), methanol, ammonia, and dimethylformamide (DMF), are miscible with water. They are recovered from the gas streams leaving the plant by water scrubbing and distillation.

The kinetics of acetylene formation always lead to the formation of higher homologues of acetylene as byproducts [46], mainly diacetylene, but also methylacetylene, vinylacetylene, and others. These compounds polymerize very easily and must be removed from the cracked gas as soon as possible. Because they are much more soluble in the solvents than acetylene, scrubbing the cracked gas with a small amount of solvent before it enters the acetylene recovery stages is sufficient.

Absorption Section (Fig. 13). Acetylene recovery is illustrated here by the BASF process. *N*-Methylpyrrolidone is used to separate the cracked gas into three streams:

1) Higher homologues of acetylene and aromatics, the most soluble part of the cracked gas. (This is a small stream of gas, which is diluted with crude synthesis gas for safety reasons and is used as fuel.)
2) Product acetylene, less soluble than the higher acetylenes, but much more soluble than the remainder of the gas
3) Crude synthesis gas (off-gas), mainly hydrogen and carbon monoxide

In the prescrubber (b) the cracked gas is brought into contact with a small amount of solvent for removal of nearly all the aromatic compounds and C_4 and higher acetylenes except vinylacetylene. This is done after the compression of the gas if screw compressors are used but before compression if turbo compressors are used because turbo compressors cannot tolerate deposits on their rotors. In the main scrubber (d) the gas is brought into contact with a much larger amount of *N*-methylpyrrolidone (NMP), which dissolves all the acetylene, the remaining homologues, and some carbon dioxide. Crude

synthesis gas (off-gas) leaves at the top of the column.

The NMP solution is degassed in several steps in which the pressure is reduced and the temperature increased. The stripper (e) operates at pressures and temperatures slightly above ambient. In this tower, the solution is put in contact with a countercurrent gas stream from the subsequent degassing step (f). This leads to the evolution of carbon dioxide, the least soluble of the dissolved gases, at the top of the stripper. The carbon dioxide is recycled to the suction side of the compression and thereby is shifted into the crude synthesis gas. The acetylene product is withdrawn as a side stream from the stripper. The *N*-methylpyrrolidone solution is then completely degassed (f) in two further steps at 110 – 120 °C, first at atmospheric, then at reduced pressure. Vinylacetylene, methylacetylene, and excess process water are withdrawn as bleed streams from the vacuum column (f). The water content of the solvent is controlled by the reboiling rate in the vacuum column. At the bottom of the vacuum column, degassing is completed, and the solvent is cooled and returned to the main scrubber (d).

The small amount of solvent from the prescrubber (b) is stripped with crude synthesis gas for recovery of the dissolved acetylene, the overhead gas being recycled to the suction side of

the compressor. The solvent is then degassed completely in the vacuum stripper (g), a column which also accepts the bleed stream from the vacuum column (f) containing the excess process water together with some higher acetylenes. The overhead vapor of the vacuum stripper contains the higher acetylenes, water, and some NMP vapor. In a side column (h) the NMP is recovered by scrubbing with a small amount of water, which is recycled to the main solvent stream. The gas is cooled (i) by direct contact with water from a cooling circuit to condense most of the water vapor. The higher acetylenes are diluted with crude synthesis gas before they enter and after they leave the vacuum pump (j). The diluted higher acetylenes, which are now at a pressure slightly above atmospheric, can be used as fuel gas, e.g., for soot incineration.

In order to minimize the polymer content of the solvent, about 2 % of the circulating flow is withdrawn continuously from the vacuum stripper circuit and distilled under reduced pressure, leaving the polymers as a practically dry cake for disposal.

The acetylene product from the process as described above has a purity of about 98.4 %, the remainder consisting mainly of propadiene, methylacetylene, and nitrogen. For most applications the purity is increased to 99.7 % by scrubbing with sulfuric acid and sodium hydroxide solutions. Table 5 compares the compositions of crude and purified acetylene. Table 6 compares the consumption and product yields per ton of acetylene for the oil quench process with those for the water quench process.

Table 5. Purity of the acetylene from the BASF process

Component	Crude acetylene, vol %	Purified acetylene, vol %
Acetylene	ca. 98.42	99.70
Propadiene	0.43	0.016
Propyne	0.75	traces
Vinylacetylene	0.05	0
1,3-Butadiene	0.05	0
Pentanes	0.01	0.01
Carbon dioxide	ca. 0.10	0
Nitrogen	ca. 0.30	0.30

4.2.2. Other Partial Combustion Processes

The main features of the BASF process described in detail above are common to all partial oxidation processes. Therefore only the differences between the BASF acetylene burner and burners used in the *Montecatini* and the *SBA processes* [41, 47] are described. These two processes have also attained some importance. The details of the acetylene recovery process depend on the properties of the solvent, but here too the basic principles are the same for all processes.

Montecatini Process . The Montecatini burner [48] has the same main components as the BASF burner: mixing unit, gas distributor, reaction chamber, and quench. The essential difference is the pressure for acetylene synthesis, which can be as high as several bar. This saves compression energy, improves heat recovery from the quench water, which is obtained at 125 °C, and is claimed to make soot removal easier because the cracked gas is scrubbed with water above 100 °C. Although it is well known [7] that acetylene decomposition is accelerated under pressure at high temperatures (> 1000 °C), the acetylene yield is comparable to that obtained at atmospheric pressure because of the short residence time in the reactor. Methanol is used at cryogenic temperatures for acetylene recovery. The main steps of the gas separation are absorption of higher acetylenes and of aromatics, absorption of acetylene, stripping of coabsorbed impurities, and desorption of acetylene.

SBA Process (of the Société Belge de l'Azote). The SBA burner [49] has the same main components as the other processes. However, it has a telescope-like reaction chamber and a device for shifting the quench up and down. Thus it is possible to adjust the length of the reaction zone for optimum residence time at any throughput. The walls of the reaction chamber are sprayed with demineralized water to prevent coke deposits. This eliminates the need to scrape the reaction chamber periodically. Acetylene recovery is carried out with several scrubbing liquids — kerosene, aqueous ammonia, caustic soda, and liquid ammonia, each with its own circuit. After soot is separated from the gas in an electrofilter, higher hydrocarbons are absorbed in kerosene or gas oil. Carbon dioxide is scrubbed in two steps, first with aqueous ammonia and then with caustic soda solution. The acetylene product is absorbed into anhydrous

Table 6. BASF acetylene process, consumption and product yields per ton of acetylene

Consumption and product yields	Oil quench	Water quench
Feed and energy requirements		
Natural gas, 36 000 kJ/m^3(STP) (LHV) *	5833 m^3 = 210 GJ	5694 m^3 = 205 GJ
Oxygen, 0.55 kWh/m^3(STP) **	3400 m^3 = 20.4 GJ	3400 m^3 = 20.4 GJ
Fuel gas	= 12.0 GJ	= 18.0 GJ
Residue oil minimum (surplus)	0.3 (1.0) t = 12.0 (40.0) GJ	
Sulfuric acid	160 kg	160 kg
Sodium hydroxide	5 kg	5 kg
N-Methylpyrrolidone	5 kg	5 kg
Electric energy **	3200 kWh = 34.9 GJ	3100 kWh = 33.8 GJ
Steam, 4 bar	5.0 t = 11.7 GJ	4.5 t = 10.5 GJ
Energy input	301.0 (329.0) GJ	287.7 GJ
Product yields		
Acetylene, 48650 kJ/kg (LHV)	1.0 t = 48.6 GJ	1.0 t = 48.6 GJ
Crude synthesis gas, 12100 kJ/m^3(STP) (LHV)	10600 m^3 = 128.3 GJ	10150 m^3 = 122.8 GJ
Coke (with residue surplus), 35 500 kJ/kg	0.3 (0.46) t = 10.7 (16.3) GJ	–
BTX (with residue surplus), 40 250 kJ/kg (LHV)	0.05 (0.12) t = 2.0 (4.8) GJ	–
Naphthalenes (with residue surplus), 38770 kJ/kg (LHV)	0.0 (0.41) t = – (15.9) GJ	–
Steam (up to 15 bar)	13.0 (14.0) t = 30.3 (32.6) GJ	1.5 t = 3.5 GJ
Energy output	219.9 (246.5) GJ	174.9 GJ
Thermal efficiency	73.0 (74.9) %	60.8 %
Energy losses, absolute per ton acetylene	81.1 (82.5) GJ	112.8 GJ

* If the natural gas contains inerts and higher hydrocarbons, the required input will remain approximately the same on a heating value basis (LHV = low heating value), but the cracked gas analyses and the crude synthesis gas analyses will differ slightly.
** Thermal efficiency of electricity production is assumed to be 33 %.

ammonia and must be scrubbed with water after desorption. All the ammonia–water mixtures are separated in a common distillation unit. This recovery scheme leads to exact separation of the various cracked gas components.

Additional Remarks. The Montecatini and SBA processes can also be operated with two-stage burners. A prequench with light hydrocarbons cools the cracked gas to about 800 °C. After a residence time at this intermediate temperature the gas is cooled down with water. In this way the heat content of the hot gases is used for further cracking of hydrocarbons to yield extra acetylene and olefins. The presence of additional components in the cracked gas requires more process steps in the gas separation units.

4.2.3. Submerged Flame Process

The submerged flame process (SFP) of BASF attracted considerable interest up to 1973 as a partial combustion process for the production of acetylene, ethylene, C_3, and C_4 hydrocarbons, and synthesis gas from feedstock of crude oil and residues, such as Bunker C oil and vacuum residue [44, 45]. Although it was abandoned at the end of 1973, the need to make the most economic use of raw materials has renewed interest in this process [50].

Oxygen compressed to 16 bar (1.6 MPa) feeds a flame that is submerged in the oil. The oil surrounding the flame is partially burnt to obtain the necessary reaction temperature and also acts as the quenching medium. This process differs from the partial oxidation processes using natural gas and lighter hydrocarbons in five main respects:

1) Crude oil can be gasified without the formation of residues, and the process can be operated under certain conditions with heavy fuel oil.
2) All the soot formed is consumed when crude oil feedstock is used, eliminating all the problems associated with the storage, disposal, or utilization of acetylene soot.
3) The heat of reaction is removed by steam generation at 8 bar (0.8 MPa).
4) The process is operated at 9 bar (0.9 MPa) so that the oxygen is the only compressed stream.

The cracked gas is formed at a pressure sufficient for economic separation.

5) The design of the cracking unit is greatly simplified because the reaction feed, fuel, and quenching medium are identical.

The process is described in detail in the literature cited; therefore, only general overviews of the cracking unit (Fig. 14) and the separation unit (Fig. 15) are shown here. The capacities of a submerged flame burner for acetylene and ethylene are 1 t/h and 1.15 t/h, respectively. To produce these quantities, 5000 m^3 (STP) of oxygen and 8 – 10 t of oil are required per hour. The cracked gas shows the following average composition (vol %, the components grouped as streams leaving the separation unit):

Main products	
Acetylene	6.2
Ethylene	6.5
Crude synthesis gas	
Carbon monoxide	42.0
Hydrogen	29.0
Methane	4.0
Inerts	0.6
Other hydrocarbons	
Ethane	0.5
Propane	0.1
Propene	1.2
Propadiene, propyne	0.7
1,3-Butadiene	0.5
Other C_4 and C_{5+} * hydrocarbons	1.5
Remainder	
Carbon dioxide	7.0
Hydrogen sulfide	0.05 – 0.5
Carbon oxide sulfide	0.03 – 0.3

* C_{5+}, five or more carbons

Unlike all other processes the submerged flame process uses low temperatures (–165 °C) to separate the off-gas, consisting of carbon monoxide, hydrogen, and methane, from the C_2 and higher hydrocarbons. On account of the acetylene in the condensed phase, extensive decomposition tests have been carried out. Whereas the cracking unit (Fig. 14) and the amine scrubbing unit have been tested by Soc. Ital. Serie Acetica Sintetica, Milan, on a commercial scale, the remaining purification units (Fig. 15) have not. However, the experience obtained with a pilot plant indicates that major difficulties are not to be expected.

The submerged flame process may become competitive because of its ability to use crude oil and especially residues and because of its low losses on the primary energy input.

Figure 15. Submerged flame process — purification unit

4.2.4. Partial Combustion Carbide Process

Calcium carbide production from lime and coal requires a large high-temperature heat input (see Section 4.3.4). In the thermal process some of the coal must be burnt to attain the necessary reaction temperature and supply the heat of reaction. The thermal carbide process was developed by BASF [7, 51] from 1950 to 1958 to eliminate the input of electrical energy necessary in the classic carbide process. Starting in 1954, a large pilot plant, with a nominal carbide capacity of 70 t/d, was operated, but in 1958 the more economical petrochemical acetylene production halted further development. Carbide production is just one way of converting coal chemically; other methods include pyrolysis, hydrogenation, and gasification. The question arises as to the conditions under which a thermal carbide process using oxygen can compete with the electric carbide process. The biggest drawback of carbide production in a shaft furnace (Fig. 16) compared to the electric carbide process is the lack of commercial-scale operational experience. Specific disadvantages are greater susceptibility to

Figure 14. Submerged flame process (SFP) — cracking unit
a) Reactor; b) Oil cooler; c) Steam generator; d) Oil recycle pump; e) Scrubber; f) Naphtha cooler; g) Naphtha separator; h) Naphtha pump; i) Spray cooler; j) Separating vessel; k) Recycle-water pump; l) Recycle-water cooler

disruption because of plugging of the furnace feed, more stringent specifications for the raw materials, more handling of solids, and the large amount of byproduct. There are two main advantages:

1) A thermal efficiency of about 50 % versus about 30 % for the electrothermal process if the thermal efficiency of electricity production is 33 %
2) Carbon monoxide production, which is desirable because carbon monoxide can be converted to synthesis gas by the water-gas shift reaction (→ Gas Production)

Table 7. Partial combustion carbide process, consumption and product yields per ton acetylene

Raw materials	
Coke, dry (88 % C)	5700 kg
Lime (92 % CaO)	3140 kg
Oxygen (98 %) 3560 m^3 (STP)	5090 kg
Total consumption	13 930 kg
Products	
Carbide (80.5 %)	2850 kg ≙ 1000 kg acetylene
Carbon monoxide 7980 m^3 (STP)	9975 kg
(CO 95.5, H_2 2.0, N_2 2.0, CO_2 0.5 vol %)	
Dust	900 kg
Losses	205 kg
Total products	13 930 kg

If the carbon monoxide is converted to synthesis gas and the electrical energy is produced from fossil fuels, production costs are about one third lower for the thermal process than for the electrical process [52] based on the pilot-plant consumption data (Table 7).

4.3. Electrothermic Processes

Because calcium carbide is produced electrothermally, the production of acetylene from this material also is discussed in this group of processes (Section 4.3.4).

Electrothermic processes have the following advantages over partial oxidation:

– The energy requirement for the formation of acetylene can be made independent of the hydrocarbons used as feedstock.
– Hydrocarbon consumption can be reduced by 50 %.
– Provided that electrical energy is available under favorable conditions (nuclear power, hydroelectric power, cheap coal) and/or the availability of hydrocarbons is limited, electrothermic processes are more economical.

In the case of acetylene formation, the electric-arc process offers optimal conditions for the endothermic reaction at high temperatures.

The development of the electric-arc process for cracking light hydrocarbons to acetylene began in 1925 in Germany. The acetylene was to be used as feedstock for butadiene production.

Figure 16. Partial combustion carbide process
a) Carbide furnace; b) Refractory brick lining; c) Charging hopper; d) Gas outlet; e) Oxygen jet; f) Tapping burner; g) Tapping chute; h) Bogey; i) Cyclone; j) Washing column; k) Desintegrator; l) Compressor

In 1940, the first commercial plant was put on stream at Chemische Werke Hüls in Marl, Germany. The Hüls process has since been improved , and the capacity raised, but it retaired the original principles [53].

Feedstock for electric-arc processes may be gaseous or liquid hydrocarbons or even solids such as coal. The design of the arc furnace and the purification section for the cracked products have to be adapted to the different feedstocks. For gaseous or gasified hydrocarbons the classical one-step process is used: the arc burns directly in the gas being cracked. For liquid and solid feeds, a one- or two-step process may be used. In the two-step process hydrogen is first heated in the arc furnace, and then liquid or solid feed is injected into the hydrogen plasma [54]. Figure 17 shows both types of arc furnaces. Because of hydrogen formation during the cracking reaction, the arc burns in a hydrogen atmosphere in both processes. The conductivity and the high rate of ion–electron recombination for hydrogen mean that arcs above a certain length cannot be operated with alternating current at normal frequency and high voltage. All commercial plants therefore run on direct current.

4.3.1. Production from Gaseous and/or Gasified Hydrocarbons (Hüls Arc Process)

The plant for the Hüls arc process includes the arc furnace section itself (Fig. 17 A), which is operated at a pressure of 1.2 bar, and a low and high pressure purification system.

Arc Furnace. A cathode, a vortex chamber, and an anode make up the arc furnace. Cathode and anode are water-jacketed tubes of carbon steel 0.8 m and 1.5 m long, respectively, and with inner diameters of 150 and 100 mm, respectively. The arc burns between cathode and anode with a length of about 1.2 m and with a current of 1200 A. The cathode is connected to the high-voltage side of the rectifier (7.1 kV) and electrically isolated from the other parts of the furnace. Between cathode and anode is the vortex chamber. The gas is injected into it tangentially at a specific velocity to stabilize the arc by creating a vortex. The arc burns in the dead zone, and the striking points of the arc on the electrodes are forced into a rapid rotation so that they only burn for fractions of a millisecond at one point, which gives the electrodes a lifetime up to 1000 h. Temperatures reach 20000 °C in the center of the arc. Because of the tangential flow of the gas, the arc is surrounded by a sharply decreasing coaxial temperature field, and the temperatures at the wall of the electrode are only 600 °C. Thermal losses are therefore limited to less than 10 % of the electrical power input of 8.5 MW.

The residence time of the gas in the arc furnace is a few milliseconds. In this interval, the hydrocarbons are cracked, mainly into acetylene, ethylene, hydrogen, and soot. At the end of the arc furnace, the gases are still at a temperature of about 1800 °C. The high heat content of this gas can be exploited for additional ethylene production by means of a prequench with liquid hydrocarbons. This lowers the temperature to about 1200 °C. Because acetylene

Figure 17. Hüls electric-arc furnaces for gaseous, liquid, and solid feed
A) One-step process; B) Two-step process

rapidly decomposes into soot and hydrogen at these temperatures, the gases must be quenched immediately with water to about 200 °C, i.e., a quench rate of 10^6 °C/s must be achieved.

The *specific energy requirement* (SER) and the acetylene yield depend on the geometry and dimensions of the furnace and electrodes, the velocity distribution of the gas, and the kind of hydrocarbon to be cracked. Once the furnace has been designed, only the hydrocarbons can be varied.

Process Without Prequench. Figure 18 shows acetylene and ethylene yields and the specific energy requirement (SER) of various saturated hydrocarbons under constant conditions without prequench. Methane shows the highest SER and acetylene yield, but the lowest ethylene yield. As the chain length is increased, both acetylene yield and SER decline, corresponding to the declining heat of acetylene formation from the various hydrocarbons.

Normally, pure hydrocarbons are not available. The results obtained from mixtures of hydrocarbons can be expressed as a function of the carbon number, which is the number of moles of carbon atoms bound in hydrocarbons per mole of the gaseous mixture. Figure 19 shows specific amounts of acetylene, ethylene, and hydrogen formed and of hydrocarbon consumed as a function of carbon number. This function enables the Hüls process to be optimized within certain limits, for example, for hydrogen output in relation to acetylene production.

Figure 18. Acetylene yield, ethylene yield, and energy consumption for various hydrocarbons in the Hüls arc process

Figure 19. Specific values for acetylene and hydrogen formation

Process with Prequench. Cracking in the prequench section is essentially an ultrasevere steam cracking process. The kind and amount of hydrocarbons used for the prequench can be varied. Figure 20 shows the specific product yield for different prequench rates for feeding methane to the arc furnace and propane to the prequench. Acetylene and hydrogen yields are unaffected, whereas ethylene shows a slight maximum and declines when the temperature is not sufficient at a given residence time. Propene shows a steady increase, and the $C_3 : C_2$ ratio is below 0.25. The relative ethylene yield from various hydrocarbons is as follows: ethane 100, propane 75, *n*-butane 72, isobutane 24, 1-butene 53.

Figure 20. Specific product yield for different prequench rates

Oil Quench. Because the gas temperature of the furnace gas after prequench is on the order of

Figure 21. Process with oil quench system
a) Heat recovery; b) Arc furnace; c) Oil recovery; d) Separation of medium-boiling compounds; e) Separation of low-boiling compounds; f) Oil regeneration

1200 °C, an oil quench system has been developed to regain about 80 % of the sensible heat content of the furnace gas as steam by heat exchange. The soot–oil mixture formed can be upgraded to a sulfur- and ash-free high-grade petroleum coke. Figure 21 shows the Hüls system with oil quench.

The Purification System. The process of purification depends on the type of the quench system. In the case of water quenching, 80 % of the carbon black is removed by cyclones as dry carbon black, the remaining 20 % as soot in water-operated spray towers. In a combined oil–water scrubbing system, aromatic compounds are removed and benzene, toluene, and xylene (BTX) are recovered in a distillation process.

Figure 22 shows the principle separation and purification steps for the furnace gas. The gas leaves the first three purification sections with a carbon black content of 3 mg/m^3 and is compressed by four-stage reciprocating compressors to 19 bar (1.9 MPa). The gas is washed in towers with water in a countercurrent flow. At the bottom of the tower, the water is saturated with acetylene, whereas the overhead gas contains less than 0.05 vol % acetylene. The acetylene–water solution is decompressed in four stages. Gas from the first decompression stage returns to the compressor to improve selectivity. The last two stages operate at 0.2 and 0.05 bar (20 and 5 kPa). The gas still contains about 10 vol % of higher acetylenes, which are removed by a cryogenic process. The higher acetylenes are liquefied, diluted with flux oil, stripped, and returned to the arc furnace together with spent hydrocarbon. A more selective solvent such as *N*-methylpyrrolidone or dimethylformamide is preferred to the water wash.

Linde and Hüls have designed an appropriate purification system. Hydrogen and ethylene are separated by well-known technology, such as the cryogenic process or pressure-swing adsorption (see → Adsorption).

Process Data. Hüls operates its plant with a mixture of natural gas, refinery gas, and liquefied petroleum gas. The carbon number varies between one and two. Table 8 shows a typical analysis of feed gas and cracked gas.

Table 8. Typical analysis of feed and cracked gas

	Feed gas, vol %	Cracked gas, vol %
C_2H_2	0.4	15.5

N_2	1.6	0.4

The Hüls plant has 19 arc furnaces, the number operated depending on the electricity supply. The arc furnaces can be started up and shut down immediately. Two large gas holders provide a storage volume of 350000 m^3 so that the purification section operates on permanent load and there is a dependable supply of products, even if the arc furnace section is operated at higher or lower load.

The plant has an annual capacity of 120000 t acetylene, 50000 t ethylene, 400×10^6 m^3 (STP) hydrogen, 54000 t carbon black and soot, and 9600 t aromatic compounds. The energy consumption is 1.5×10^6 MW h/a.

Specific data for consumption of hydrocarbons and energy and the production of byproducts per ton of acetylene produced are as follows:

Hydrocarbons to the arc furnace	1.8 t
Hydrocarbons for prequench	0.7 t
Energy for the arc furnace	9800 kW h
Energy for gas purification	2500 kW h
Ethylene	0.42 t
Hydrogen	3300 m^3 (STP)
Carbon black and soot	0.45 t
Aromatics	0.08 t
Residue	0.12 t
Heating gas	0.12 t

Figure 22. Principal separation and purification steps for the furnace gas of the Hüls arc process

4.3.2. Production from Liquid Hydrocarbons (Plasma Arc Process)

Two different plasma furnaces, each with the appropriate reactor for the cracking of liquid hydrocarbons, were developed by Hoechst and Chemische Werke Hüls in close cooperation. Both units were tested on an industrial scale at a power level of 8 – 10 MW [55]. However, neither process has actually come into use for acetylene production on account of the economics.

The scheme of the plasma generator used by Hüls is shown in Figure 17 B. The unit consists of three parts: the arc furnace, the reactor, and the quench system. The arc burns over a length of 1.6 m at 7 kV d.c. and 1.2 kA, resulting in a power input of 8.5 MW. It is stabilized by hydrogen injected tangentially through the vortex chamber. The thermal efficiency of the furnace is ca. 88 % of the electrical power input. The hydrogen plasma jet passing through the anode nozzle has an energy density of 3.5 kW h/m^3(STP), corresponding to an average temperature of 3500 K. The liquid hydrocarbons (e.g., crude oil) to be cracked are injected into the cylindrical reactor to achieve good mixing with the plasma jet and to avoid the formation of carbonaceous deposits on the wall. Within several milliseconds the hydrocarbons are heated and cracked to acetylene, ethylene, hydrogen, soot, and other byproducts before the mixture is quenched with oil to 300 °C. The acetylene ratio can be adjusted by varying the residence time. By operation of an oil quench with the high-boiling residue of the crude oil, 80 % of the sensible heat content of the cracked gas can be recovered as steam. The soot is taken up by the quench oil and is removed from the system as an oil–soot dispersion having 20 % soot concentration. The unconverted vaporized fractions of the oil are condensed in oil scrubbers at a lower temperature, simultaneously cleaning the gas of the aromatic components and fine soot. These oil fractions are recycled to the reactor and the quench system, respectively.

Tests were carried out with a variety of hydrocarbons from propane to naphtha, but mainly with crude oil and residue oils. The cracking results depend on the chemical nature of the feed. Consumption figures and yields for various feedstocks are given in [55]. For high-boiling petroleum fractions, the acetylene and ethylene yields increase with the content of low-boiling components in the feed (see Fig. 23). Consumption and byproduct yields per ton of acetylene for a Libyan crude oil are summarized below:

Consumption	
Crude oil consumed	3.5 t
Power (d.c.)	10500 kW h
Byproducts	
Ethylene	0.46 t
Hydrogen (99.9 %)	1100 m^3 (STP)
Fuel gas	0.74 t
Soot – oil mixture (20 % soot)	1.2 t

Hoechst used a high-intensity three-phase a.c. arc furnace at 1.4 kV and 4.2 kA, giving a power input of 10 MW [55]. The thermal efficiency was 90 %. Because of the high amperage the graphite electrodes had to be replenished continually. The generator was lined with graphite. Different reactor designs for ethylene: acetylene ratios of 0.5 and 1.0 were developed by varying the mixing intensity of the hydrogen plasma jet with the liquid hydrocarbon. The tests were carried out with naphtha feed (see Table 9). The cracked gas was quenched with residue oil, in a manner similar to that described in the Hüls process.

Figure 23. Acetylene and ethylene yields as a function of the low-boiling components

The acetylene concentration in the Hüls process and the Hoechst process was ca. 14 vol % so that in principle the same acetylene separation process can be used as described above for the arc process.

4.3.3. Production from Coal (Arc Coal Process)

Numerous laboratory tests for the conversion of coal to acetylene using the arc or plasma processes have been carried out since the early 1960s [56]. The results can be summarized as follows:

- Acetylene yields up to 30 % can be obtained.
- Because of the rapid heating of the coal in the plasma jet, a higher total gas yield can be achieved than is indicated by the volatiles of the coal measured under standard conditions.
- Hydrogen (instead of argon) plasma gas considerably increases the acetylene yield.

The AVCO arc furnace (Fig. 24) consists of a water-cooled tungsten-tip cathode and a water-cooled anode [57]. The arc is stabilized by a magnetic field surrounding the anode, forcing the anode striking point of the arc to rotate rapidly and so avoiding burnthrough. The dried and finely ground coal is injected by means of a hydrogen gas flow around the cathode. Additional gas without coal is introduced around the cathode and at the anode as a sheath. On passing the arc zone the coal particles are heated up rapidly. The volatiles are released and are cracked to acetylene and byproducts, leaving a residue of fine coke particles covered with soot. After a residence time of some milliseconds the gas–coke mixture is quenched rapidly with water or gases. The use of a prequench system similar to that of the Hüls arc process was also tested. The system pressure can be varied between 0.2 and 1.0 bar (20 and 100 kPa).

Figure 24. Principal scheme of the AVCO plasma furnace for the pyrolysis of coal

Table 9. Consumption and yield per ton of acetylene for the Hoechst arc process and naphtha feed for different reactor designs

	Low ethylene yield	High ethylene yield
Consumption		
Naphtha	1.92 t	2.50 t
Quench oil	0.53 t	0.63 t
Energy(2-phase a.c.)	9300 kW h	10500 kW h
Byproducts		
Ethylene	0.5 t	0.95 t
Hydrogen	1450 m^3 (STP)	1500 m^3 (STP)
Soot–oilmixture(20 % soot)	0.75 t	1.00 t

Hüls' pilot plant uses the same plasma furnace as for the crude oil cracking, but with 500 kW of power [58]. The dried and ground coal is injected into the plasma jet, and the coal is cracked to acetylene and byproducts in the reactor. The reactor effluent can be prequenched with hydrocarbons for ethylene production or is directly quenched with water or oil. Char and higher boiling components are separated by cyclones and scrubbers, respectively. The problem in the reactor design is to achieve thorough and rapid mixing of the coal with the plasma jet and to avoid forming carbonaceous deposits on the wall. Smaller amounts of deposits can be removed by periodic wash cycles with water. Operation times of 2.5 h by AVCO and 5 h by Hüls have been reported.

Figure 25. Effect of the energy density of the plasma on the cracking of coal (AVCO)

Experiments published by Hüls and AVCO show that at the optimal residence time the energy density of the plasma jet, the specific power, and the pressure all greatly affect the acetylene yield (Fig. 25 and Fig. 26). Other parameters affecting the yield are the amounts of volatiles in the coal and the particle size. The lowest figures for the specific energy consumption published by AVCO are of the order of 27 – 37 % based on water-free coal.

Figure 26. Acetylene yield and specific energy requirement as a function of pressure (Hüls)

In addition to acetylene, the exit gas contains considerable amounts of CO, depending on the oxygen content of the coal. Because nitrogen and sulfur are present in the coal, other byproducts are HCN, CS_2, COS, and mercaptans. The gas separation system is therefore designed accordingly [59]. Depending on the hydrogen content of the coal, the process is either self-sufficient in hydrogen or has a slight surplus. The total gas yield of the coal based on a volatile content in the coal of 33 % is up to 50 %. Thus 50 % of the coal remains as char. Tests with a view to using this char in the rubber industry have been unsuc-

cessful so far. Thus the char can be used only for gasification or as a fuel.

In all the processes under development, the production of ethylene from coal requires several process steps (Fig. 27), resulting in a high capital demand for a production plant. In contrast, the acetylene production from coal arc pyrolysis is straightforward, leading to lower investment costs. Demonstration units on a higher power level are therefore scheduled by both AVCO and Hüls.

4.3.4. Production from Calcium Carbide

At present, the generation of acetylene from calcium carbide (→ Calcium Carbide) is of primary importance for welding and for the production of carbon for batteries. The particular raw-material situation and the use of special processes are two common reasons for continuing to use acetylene generated from carbide in the chemical industry.

The reaction of calcium carbide and water to form acetylene and calcium hydroxide is highly exothermic:

$$CaC_2 + 2\ H_2O \rightarrow C_2H_2 + Ca(OH)_2 \quad \Delta\ H = -129\ \mathrm{kJ/mol}$$

The acetylene generator used for commercial production must therefore be designed to allow dissipation of the heat of reaction. In the event of inadequate heat dissipation, for example, when gasification proceeds with insufficient water, the carbide may become red-hot. Under certain circumstances (including increasing pressure), this may cause the thermodynamically unstable acetylene to decompose into carbon and hydrogen. (For safety precautions see Chap. 5.) Carbide for the production of acetylene is used in the following grain sizes (mm): 2 – 4, 4 – 7, 7 – 15, 15 – 25, 25 – 50, 50 – 80. This classification is virtually identical in most countries: DIN 53922 (Germany); BS 642:1965 (United Kingdom); JIS K 1901 – 1978 (Japan); Federal Specification 0–6–101 b/GEN CHG NOT 3 (United States). In addition, grain size 0 – 3 is used for the dry generation of acetylene.

Pure calcium carbide has a yield number of 372.66. This means that the gasification of 1 kg of carbide yields 372.66 L acetylene at 15 °C and 1013 mbar (101.3 kPa). Commercially available carbide has a yield number of 260 – 300.

A distinction is made between two groups of acetylene generators (with continuous rates of production greater than 10 m^3 acetylene per hour): the wet type and the dry type.

In *wet generators*, the acetylene is converted with a large water excess. In most cases, a lime slurry containing 10 – 20 wt % calcium hydroxide is obtained. The heat of reaction increases the temperature of the generator water and is removed from the reactor with the lime slurry.

In *dry generators*, the water mixed with the carbide is just sufficient for chemical reaction and for dissipating the heat of reaction. The calcium hydroxide is obtained in the form of a dry, easily pourable powder having a residual moisture content of 1 – 6 %. The heat of reaction is dissipated by evaporation of part of the generator water.

Generators are classified according to their working pressure as either low or medium pressure. This classification is governed by the regulations concerning acetylene plants and calcium carbide storage facilities (*Acetylenverordnung*) [60] issued by Deutscher Acetylenausschuß (German acetylene committee) and the associated technical rules for acetylene plants and calcium carbide storage facilities *TRAC* (*Technische Regeln für Acetylenanlagen und Calciumcarbidlager*) [61]. The *Acetylenverordnung* and *TRAC* constitute a comprehensive set of rules for handling acetylene. Recommendations in other countries (e.g., United States) deal only with some aspects, such as safety precautions [62].

Low-pressure generators are designed for a maximum allowable working pressure of 0.2 bar. They must be rated for an internal pressure of at least 1 bar. Lower pressure ratings are possible if proof is given in each particular case that the generator can withstand the expected stress (maximum working pressure, water filling, agitator, etc.; *TRAC 201*).

Medium-pressure generators have a maximum allowable working pressure of 1.5 bar. They must be rated for an internal pressure of 24 bar. A design pressure of 5 bar suffices whenever the generators are equipped with rupture disks of a defined size and specified response pressure (3 – 4.5 bar, *TRAC 201*).

Figure 27. Alternative routes from coal to ethylene and acetylene

4.3.4.1. Wet Generators

Wet generators are used primarily for the production of small amounts of acetylene, e.g., for welding purposes. Wet generators work by one of three different principles [63]:

1) The *carbide-to-water principle,* where the carbide is mixed with a large excess of water at a rate corresponding to the gas withdrawal rate. Most generators work by this principle.
2) The *water-to-carbide principle* (drawer type generators), where water is added at a controlled rate to the carbide, which is held in a replaceable container (drawer).
3) The *contact principle* (basket generators), where the carbide, which is held in a basket, is immersed into the generator water. This type is designed so that the water drifts off the basket as a result of the gas pressure at low gas withdrawal rates and, conversely, returns to the basket when gas withdrawal rates increase.

Medium-Pressure Generators. The Messer Griesheim MF 1009 is a typical carbide-to-water generator (Fig. 28).

The carbide skip (a) is filled with carbide of the 4 – 7 grain size. The skip is connected by gas-tight gates to the hopper (b) and is purged of air by nitrogen or acetylene. The carbide drops into the hopper (b) and is fed continuously by the feeding system (c) to the gasification chamber (d). The gasification chamber contains water up to a level defined by the generator capacity and is equipped with an agitator (e) for whirling the lime slurry. The heat evolved in gasification heats the generator water. For continuous operation the water temperature must not exceed 90 °C; therefore, fresh water is admitted continuously to the gasification chamber. If the defined water level is exceeded, the slurry valve (f), controlled by a float, opens, allowing the excess water and the lime slurry to be discharged from the generator.

The acetylene generated collects above the water and is withdrawn. The feeding system (c) is controlled by the gas pressure, i.e., the rate at

which carbide drops into the gasification chamber varies directly with the rate of gas withdrawal.

Figure 28. Medium-pressure wet generator
a) Carbide skip; b) Hopper; c) Feeding system; d) Gasification chamber; e) Agitator; f) Slurry valve, g) Safety device

The carbide stock in the hopper (b) is sufficient for about one hour, but the skip (a) can be refilled with carbide and replaced on the hopper so that continuous operation is possible. The wet generator described has a continuous hourly output of 75 m^3 of acetylene. The skip holds 1000 kg of carbide.

Low-Pressure Generators. The working principle of the low-pressure carbide-to-water generators is very similar to that of the medium-pressure carbide-to-water generator described above. In most cases, a downstream acetylene holder, normally of the floating gas bell type, is provided. In contrast to the medium-pressure generator, in which the carbide feed rate is controlled by the acetylene gas pressure, the feed rate in the low-pressure generator is controlled by the position of the bell in the acetylene holder, i.e., by the gas quantity.

Products. The acetylene generated in the wet generator can be used for welding, often without further purification. In certain cases, coke- or gravel-filled purifiers or a wet scrubber are connected downstream from the generator for separating solid or liquid particles. Before it is fed to a synthesis unit, the acetylene must be purified chemically (see Section 4.3.4.3).

The lime slurry formed is fed into pits. Here, the calcium hydroxide settles in the form of a lime dough containing 35 – 75 wt % water (wet lime, carbide lime dough). This dough is used as carbide lime.

4.3.4.2. Dry Generators

Dry generators are mainly used for the production of large quantities of acetylene for chemical synthesis.

Compared to the wet generator, the primary advantage of the dry generator is that the dry calcium hydroxide formed as a byproduct can be used in other processes more easily, more cheaply, and in a more diversified way than the lime slurry obtained in the wet generator [64]. Moreover, lime recycling into the carbide production process is only possible with dry calcium hydroxide.

A high gasification rate and the elimination of the risk of overheating were originally the most important criteria for the design of dry generators. Early designs of dry generators worked by continuous renewal of the reaction surfaces of coarse carbide with the aid of rotating drums, blades, vibrating screens, and similar equipment.

Typical examples are the early generator of Shawinigan Chemicals [65] and the Piesteritz dry generator [66].

Although a number of factors affect the gasification rate of carbide, e.g., density, porosity, and crystalline structure, above all it is the specific surface that affects the carbide gasification rate the most. Hence, dry generators work with finely ground carbide (0 – 3 mm), which gasifies in a fraction of the time needed for coarse carbide. The result is a high space–time yield.

A typical application of this principle is the large-scale *Knapsack dry generator*, which was developed at the Knapsack works of Hoechst. This type of generator is used worldwide and is described in more detail below (Fig. 29).

Carbide of the grain size 0 – 3 falls from the chain conveyor (a) into the subdivided feed bin (b). The chain conveyor is loaded with material from the carbide bin. Because of the recirculating stream of carbide the feed bin (b) is full at

all times. The carbide layer in the feed bin (b) acts as a gas seal between the generator and the carbide conveying system.

Figure 29. Knapsack dry generator
a) Chain conveyor; b) Feed bin; c) Star wheel; d) Carbide feed screw; e) Generator; f) Lime lockhopper; g) Lime discharge screw; h) Lime scraper; i) First scrubbing tower; k) Second scrubbing tower; l) Dip seal

The carbide is fed to the generator (e) via the star wheel (c) and the carbide feed screw (d). The largest generator of this kind built to date has a diameter of 3.5 m and an overall height of approximately 8.0 m. The generator has up to 13 circular trays. These are so designed as to leave alternate annular gaps on the shell side and at the central agitator shaft. The agitator shaft moves stirrer paddles across the trays.

The carbide first reaches the uppermost tray where the generator water is also admitted. The reaction mixture consisting of carbide, water, and calcium hydroxide is pushed by the stirrer paddles towards the outer edge, drops on to the second tray, returns towards the center, etc. When it reaches the last tray, the carbide has been fully gasified. The calcium hydroxide, which still contains up to 6 % water, drops into the lime lockhopper (f). Here, a lime layer two meters deep serves as the gas closure between generator and lime conveying system. The lime is withdrawn continuously.

The gas leaving the generator through the lime scraper consists of 25 % acetylene and ca. 75 % water vapor. The water vapor is the result of dissipating the major portion of the reaction heat. Depending on the generator load, up to several hundred kilograms of lime hydrate dust are carried along with the acetylene. The lime scraper (h) retains the major portion of this dust and returns it to the generator. The remainder is sent together with the gas into the first scrubbing tower (i). Here, lime slurry is sprayed into the hot acetylene gas (ca. 90 °C) to scrub out the lime dust; part of the water vapor condenses because of the simultaneous cooling. In the second scrubbing tower (k), the acetylene is sprayed with atomized water to cool the gas below 40 °C; additional water vapor condenses here. Any ammonia still present in the gas is also removed.

The acetylene leaves the generator via the dip seal (l). It still contains certain impurities in the form of sulfur and phosphorus compounds.

The Knapsack dry generator is suitable for a carbide throughput of 15 t/h, corresponding to an acetylene quantity of 3750 m^3/h. During this process, about 17.5 t of calcium hydroxide per hour are obtained. The pressure in this low-pressure generator amounts to approximately 1.15 bar (115 kPa).

The dry generator of Shawinigan Chemicals, Montreal [67], also processes finely ground carbide and has a variety of applications. It consists of several superimposed troughs. Carbide and water are fed into the uppermost trough. The reacting mixture, which is constantly kept in motion by blades, flows over a weir onto the trough below, etc. At the uppermost trough, water is admitted at such a rate that carbide-free calcium hydroxide can be withdrawn at the lowermost trough. The generated acetylene is purified in two scrubbing towers and cooled.

The calcium hydroxide formed (carbide lime) has a wide range of applications, e.g., in the building industry (for preparing mortar, cement, etc.), in the chemical industry (for neutralization and for recycling to the carbide furnace), in agriculture (as fertilizer), and for water purification and waste water treatment [64].

4.3.4.3. Acetylene Purification

During the gasification of carbide with water, gaseous compounds become mixed with the acetylene, and these must be removed because they have a harmful effect on the downstream chemical synthesis processes. The impurities are mainly sulfur and phosphorus compounds. They can be removed by one of the following purification processes.

In the first process, *dilute chlorinated water* is used as the oxidizing agent. The chlorine concentration of the water is limited to 1.5 g/L to prevent the formation of unstable chlorine compounds, which present an explosion hazard. The chlorine scrubbing step is followed by a caustic soda scrubber to remove the hydrogen chloride formed during the oxidation process. The disadvantage of this purification process is that considerable quantities of scrubbing water are produced.

The second process uses 98 % *sulfuric acid* as the oxidizing agent [68]. Because very small quantities of sulfuric acid are admitted, it is difficult to dissipate the heats of absorption and reaction. Heating the acetylene results in increased formation and settling of polymerization products in the purification stage. For this reason the gas requires additional cooling in the event that the acetylene contains appreciable quantities of impurities. Moreover, it is recommended that a second scrubbing tower be kept on standby if a high onstream factor is desired (e.g., 91 % $\triangleq$ 8000 h/a operating time).

The sulfuric acid scrubber is followed by a caustic soda scrubber, in which the sulfur dioxide formed during oxidation is removed.

The main advantage of this purification method is that virtually no waste water is obtained. The small amount of polluted, highly concentrated sulfuric acid can be used, for example, in fertilizer plants.

These two purification processes yield the following acetylene purities (by volume):

Acetylene	> 99.5 %
Sulfur, as H_2S	< 10 ppm
Phosphorus, as H_3P	< 10 ppm

As a result of the extremely good sorption properties of the concentrated sulfuric acid, very pure acetylene can be expected.

4.4. Other Cracking Processes

4.4.1. Thermal Cracking By Heat Carriers

Well-known processes using heat carriers, such as the Wulff and Hoechst high-temperature pyrolysis (HTP) processes, are no longer used because they require refined petrochemical feedstocks such as naphtha and liquid petroleum gas. The Wulff process uses refractory material as the heat carrier, whereas the Hoechst HTP process uses hot combustion gases.

Newer processes, which are able to convert crude and heavy distillates into olefins and considerable amounts of acetylene, are still in the pilot-plant stage. These processes include the advanced cracking reactor process developed by Kureha, Chiyoda, and Union Carbide, using high-temperature superheated steam, and Dow's partial combustion cracking process, using hot combustion gases produced from oxygen and fuel oil as the heat carrier.

Figure 30. High-temperature pyrolysis (HTP) process

Wulff Process [69 70, p. 58]. This process is based on indirect heat transfer, an approach fundamentally different from the partial-oxidation and electric-arc processes. The hydrocarbon feed is cracked in refractory ovens previously heated by combustion gas. After cracking, the products are quenched outside the reactor. Soot formation is a serious problem because the feed cannot be heated as rapidly as in the partial-oxidation or arc processes. This problem can be diminished by using a feed with a higher hydrogen:carbon ratio. However, methane is not suitable because of the high temperature and high heat of reaction required, resulting in a low conversion rate. Thus the best feed for the Wulff process is ethane or propane.

Hoechst High-Temperature Pyrolysis (HTP) Process (Fig. 30) [1 70, p. 55, 71]. This is a two-stage process. In the first stage, heat is produced in the burner by the combustion of residual cracked gas from the acetylene recovery section (CO, H_2, CH_4) with oxygen. Immediately after combustion, the temperature is about 2700 °C; this is moderated to about 2300 °C by the injection of steam before the reactor is entered. In the second stage, the feedstock naphtha is injected, and the adiabatic cracking reaction takes place. A final temperature of about 1300 °C is reached: This determines the cracked gas composition. By varying the feed rate of naphtha the acetylene–ethylene ratio can be altered from 30 : 70 to 70 : 30. However, thermodynamic and economic considerations show that the optimum ratio is 40 : 60.

After a reaction time of a few milliseconds the cracked gas is quenched to approximately 250 °C by the injection of cracked oil from the process. The oil absorbs heat from the cracked gas and is passed through waste heat boilers, raising the steam pressure. No soot is formed in this process, even when crude oil is used as feed because of the high steam content of the carrier gas.

After the oil crisis of 1973 the process became uneconomical in spite of its high thermal efficiency, and in 1976 it was shut down after 15 years of operation. However, one unit is still running in Czechoslovakia.

Kureha, Chiyoda, Union Carbide Advanced Cracking Reactor (ACR) Process [72]. To avoid dependence on oil refineries or gas processors for the supply of feedstocks, processes for directly cracking crude oil have been developed by various companies for the production of olefins. Some of these processes operate at reaction temperatures intermediate between those of the usual crack processes for olefins and those for acetylene. The ACR process (Fig. 31) uses a multi-port burner to produce a heat carrier

Figure 31. Advanced cracking reactor process (ACR)

gas of 2000 °C by the combustion of $H_2 - CH_4$ mixtures with oxygen in the presence of steam preheated to 800 °C.

The oil to be cracked is introduced through nozzles into the stream of carrier gas and passes into an advanced cracking reactor, where the reaction takes place adiabatically at 5 bar (0.5 MPa). The initial temperature is 1600 °C; the final temperature at the exit of the reactor is 700 – 900 °C after a residence time of 10 – 30 ms. The cracked gas is quenched by oil in an Ozaki quench cooler (Fig. 32), where steam production up to 120 bar (12 MPa) is possible. This particular boiler design was developed for a high heat transfer rate without coke formation on the exchanger surfaces. Yields reported for Arabian light crude oil are 11.2 wt % hydrogen and methane, 40.7 wt % olefins, and 4.2 wt % acetylene. The acetylene yield is about ten times higher than in usual olefin processes.

Figure 32. Ozaki quench cooler

Dow Partial Combustion Cracking (PCC) Process [72]. The basic idea of this process is to reduce coking and soot formation considerably when heavy feeds are cracked and when hydrogen is present in the reaction mixture. The PCC process (Fig. 33), which accepts crude oil and heavy residue as feedstock, attains a high partial pressure of hydrogen in the reaction zone by recycling the quench oil (produced in the process) to the burner where it is partially oxidized to yield synthesis gas. Thus there is no need to find a use for the quench oil as in the case of the ACR process. Starting from residual oil boiling above 343 °C, yields are given as 12.4 wt % methane, about 38 wt % alkenes, and 2.5 wt % acetylene. This is seven to eight times more acetylene than that obtained from a steam cracker, but less than the acetylene yield of the ACR process, because of a residence time in the reaction zone which is three to ten times longer.

4.4.2. Acetylene as a Byproduct of Steam Cracking

In a steam cracker saturated hydrocarbons are converted to olefinic products such as ethylene and propene. Besides these desired components, acetylene and many other products are formed in the cracking process (Fig. 36). The concentration of acetylene depends on the type of feed, the residence time, and temperature (cracking severity: expressed as conversion or propene/ethylene ratio P/E). Typical data are given in Table 10. The acetylene concentration in the off-gas from the furnace varies between 0.25 and 1.35 wt %. In certain cases of propane and butane cracking the the raw gas can contain up to 2.1 wt % acetylene with corresponding very low amounts of propyne and propadiene. The corresponding content of acetylene in the C_2 frac-

Figure 34. Acetylene recovery process [77]

tion is about 0.4 – 2.5 wt %. An ethylene plant producing 400 000 t/a ethylene produces 4500 – 11 000 t/a acetylene. The acetylene is removed by catalytic selective hydrogenation or solvent extraction. Today the dominating acetylene removal process is selective hydrogenation.

Acetylene Hydrogenation. Most ethylene plants are equipped with a hydrogenation unit. Acetylene is converted selectively to ethylene on a Pd-doped catalyst. Whereas in the past mainly Ni catalysts were used, today Pd catalysts are doped with other metals such as silver to improve selectivity [73]. Typical process conditions are temperatures of about 40 – 120 °C, pressures of 15 – 40 bar and space velocities of 1000 – 120 000 kg L^{-1} h^{-1}. Depending on the type of feed and the plant, there are several process options:

1) Front-end hydrogenation (C_{2-} stream containing H_2, CO, methane, C_2H_2, C_2H_4 and C_2H_6)
2) Raw-gas hydrogenation (hydrogenation before C_2/C_3 separation, stream containing H_2, CO and all hydrocarbons of the raw gas after cracked gas compression).
   This variant of front-end hydrogenation is only used in gas crackers where the content of C_{3+} hydrocarbons is comparable low.
3) Tail-end hydrogenation (pure C_2 stream containing C_2H_2, C_2H_4, and C_2H_6; separate addition of an equimolar amount of hydrogen is necessary)

Typical specifications for acetylene content in the ethylene product are < 2 ppm with a tendency to further reduction to < 1 ppm.

General aspects of the process and the catalyst requirements are reviewed in [73 – 76] (see also → Ethylene, Chap. 5.3.2.2).

Acetylene Recovery. Acetylene is extracted from the C_2 fraction of the steam cracker. The solvent must fulfil the following criteria:

– Melting point lower than the dew point of the feed gas
– High solubility of acetylene at a temperature near the dew point of the C_2 fraction
– High acetylene selectivity ([9, 11])
– High chemical and thermal stability

- No foaming tendency due to traces of hydrocarbons
- Low toxicity
- Low vapor pressure at the operating temperature

After testing many solvents, including DMF, NMP, and acetone, the most suitable solvent for such a process proved to be DMF. The solubility of acetylene as a function of temperature is shown in Figure 5.

The process for the recovery of high-purity acetylene is shown in Figure 34 [77]. The gaseous C_2 mixture, consisting of ethylene, ethane, and acetylene, is fed to the acetylene absorber; the gas stream is contacted with counterflowing lean DMF at a pressure of 0.8 – 3.0 MPa. The process is suitable for the full pressure range prevailing in any of the known ethylene processes. The entire acetylene and some of the ethylene and ethane are dissolved by the solvent. Water and carbon monoxide decrease the solubility of acetylene. Furthermore, water causes hydrolysis of DMF, resulting in additional formation of carbon monoxide. Entrainment of DMF at the top of the column is avoided by a reflux stream. The purified C_2 fraction, containing < 1 ppm of acetylene, is fed to the C_2 splitter. The rich solvent stream is sent to the ethylene stripper, which operates slightly above atmospheric pressure. Ethylene and ethane are stripped off and recycled to the first stage of the cracked gas compression. Any acetylene entrained with the overhead gas is recovered by washing with cold solvent at the top of the stripper. In the acetylene stripper, pure acetylene is isolated from the top of the column. After cooling and heat recovery, the acetylene-free solvent is recycled to the absorber and ethylene stripper. The acetylene product has a purity of > 99.8 % and a DMF content of less than 50 ppm and is available at 10 kPa and ambient temperature.

The material balance and the utilities consumption of an acetylene recovery unit are listed in Tables 11 and 12. At present, more than 112 000 t/a of petrochemical acetylene from twelve olefin plants worldwide is recovered by this technology. With a big drop in the total acetylene market in 2001, the market decreased on average by 6.8 % per year from 1998 to 2003, and only a marginal growth rate is expected until 2009 (max. 2 % per year) [135]. For this reason during the last five years (2006) no new acetylene recovery facilities have been erected. Only some existing plants were expanded. In North America, for example, there are currently only two major companies producing acetylene as byproduct of ethylene production, i.e., Dow Chemical in Taft, LA, and Petroment at Varennes in Canada [136]. Figure 35 shows an industrial plant with a design capacity of 14 400 t/a of high-purity acetylene.

Table 12. Consumption of utilities for an acetylene recovery process operating on the C_2 fraction from a plant producing 400 000 t/a C_2H_4 (Linde) [78]

Plot area, m × m	15 × 40

A material balance for ethylene plant outputs including acetylene extraction or hydrogenation is shown in Figure 36 [79]. The economic evaluation shows that petrochemical acetylene remains attractive even if the price of ethylene is doubled. It is economical to retrofit acetylene absorption in an existing olefin plant equipped with a catalytic hydrogenation. Isolation of acetylene obtained as an unavoidable byproduct of ethylene production is the economically most attractive route to cover acetylene demand.

A similar process is available for propyne (see Chap. 7)

5. Safety Precautions, Transportation, and Storage

General literature is given in [10, 80, 81].

5.1. General Safety Factors and Safety Measures

Decomposition and Combustion. Acetylene is thermodynamically unstable under normal conditions. Decomposition into carbon and hydrogen can achieve temperatures of about 3100 °C, but due to formation of other products, the temperature reached adiabatically is 2800 – 2900 °C. The decomposition can be initiated by heat of reaction, by contact with a hot body, by an electrostatic spark, by compression

* Chemical grade

heating, or by a shock wave. The decomposition induced by heating the wall of the container or pipe is very sensitive to the pressure, the size and shape of the container or the diameter of the pipe, the material of the container, and traces of impurities or other components. Solid particles such as rust, charcoal, alumina, and silica can lower the ignition temperature compared to clean steel pipe.

Decomposition gives rise to different scenarios:

- Working range I (deflagration): a flame produced by decomposition or combustion and propagates at a velocity below the velocity of sound into the unconverted gas (pressure rises simultaneously in front of and behind the flame front)
- Working range III (detonation): the flame propagates at ultrasonic velocity into the unconverted gas (shock wave between low pressure in the unconverted gas and high pressure in the converted gas)
- Working range II (intermediate between I and III): often the propagation velocity of a deflagration is not constant (it increases with increasing density, temperature, and turbulence), and therefore a change from deflagration to detonation is observed

As consequence, design criteria for piping and other components are proposed for the different working ranges and depend on the diameter of the pipe. Limit lines for deflagration and detonation are given in [82] on the basis of the work of Sargent [83]. An extended Sargent diagram is shown in Figure 37.

Figure 37. Detonability limits of acetylene [83, 88]
A) Deflagration limit; B) Detonation limit
Detonation limits: a) Thermal ignition in a plain pipe (a_1 melting wire, 20 – 80 J; a_2 detonator cup, ≈2400 J); b) Thermal ignition plus orifice; c) Ignition by chemical reaction in a shock wave; d) Range of possible quasi-detonation depending on ignition energy of shock wave; x) and y) Limiting ignition pressure for thermal ignition with melting Pt wire and with detonator cup, respectively

The limits are influenced by the method of ignition (e.g., melting wire or a detonator cap). Changing the method of ignition from a melting Pt wire (Reppe) to the exploding wire ignitor (ignition energy ca. 70 J) used by BAM resulted in lower stability pressures for acetylene mixtures [84] and pure acetylene [85] (Table 13). A description of the experimental setup can be found in [134].

Mixtures of acetylene with methane have higher stability pressures than those with nitrogen or hydrogen. The phlegmatizing influence of foreign gases increases in the order $H_2 < N_2 < CO_2 < NH_3$, which corresponds to the heat capacities of these gases [134]. For $C_2H_2 - C_2H_4$ mixtures the stability pressure rises with increasing ethylene fraction. However, a significant effect can be observed only at C_2H_2 contents $<$ 50 % [134]. Further information on the effect of additional gases on acetylene decomposition is given in [86]. The dependence of stability pressure on the energy of the ignition source has led to ongoing discussion about its relevance for industrial design and operations [87].

Figure 38. Decomposition pressure versus ignition energy for unsaturated hydrocarbons

Figure 38 shows the decomposition pressure of acetylene, propyne, and propadiene as function of ignition energy. This relationship is the basis for the safe design of processes for the recovery of acetylenic components (see Section 4.4.2 and Chap. 7). Additional investigations have been published on the dependence of deflagration pressure on the flow in pipes [88] and the decomposition of high-pressure acetylene in branched piping [89]. Solid acetylene is not critical with regard to decomposition, provided it is the only material involved [7]. In liquid oxygen, solid acetylene can readily ignite on mechanical impact and react violently [90]. Recommendations for equipment used in gas welding and cutting technology, such as rubber hoses, safety devices, and flame arresters, are given in [91 – 93].

Combustion of Acetylene in Oxygen (Air). The reaction of acetylene and oxygen at 25 °C and 1 bar to form water and CO_2 generates 1255.6 kJ/mol. Temperatures of around 3100 °C can be reached. Figure 39 shows flame temperatures and flame front velocities for mixtures of oxygen with hydrocarbons [94].

Figure 39. Flame temperatures and ignition velocities of acetylene–oxygen mixtures and mixtures of other hydrocarbons with oxygen

Acetylene allows the highest temperatures and flame front velocities to be attained. The maximum temperature is very sensitive to the mixing ratio, which also determines whether a reducing, neutral, or oxidizing flame exists (Fig. 40).

Fundamental safety data for acetylene–air and acetylene–oxygen mixtures are listed in Table 14. At atmospheric pressure and 25 °C mixtures of 2.4 – 93.0 vol % acetylene in oxygen are explosive; the possibility of self-decomposition at high acetylene must also be taken into account. A large explosion at Acetylene Services Company (ASCO) in the USA in 2005 was caused by accumulation of acetylene in the water-pipe system. Most probably the contact of acetylene with the hot surface of a propane heater caused the explosion [95]. A comparison

Table 13. Stability pressure (bar) of acetylene and acetylene mixtures for two methods of ignition and pressure increase [84, 85]

Mixture	Ignition method		p_{ex}/p_a
	Reppe	BAM	(BAM)

* Stoichiometric mixture.

Handling of Acetylene. For pure acetylene the prescribed safety instructions, for example, the *Technische Regeln für Acetylenanlagen und Calciumcarbidlager* (Technical regulations for acetylene plants and calcium carbide depots), *TRAC,* [97], have to be strictly followed. The former *Acetylenverordnung* (Decree about acetylene) [53] in Germany has been replaced by the more general *Betriebssicherheitsverordnung* (Decree about safety in plants) [97] as of January 1, 2003. However, it is not possible to formulate general safety instructions for the great variety of chemical processes with acetylene as reaction component under diverse reaction conditions.

Both handling acetylene and experiments with it necessitate critical examination of sources of possible danger. The literature cited can only serve as an aid to decisions on precautions. The safety regulations mentioned above have been determined in experiments with well-defined apparatus dimensions (length, diameter, geometry). For other dimensions they can only serve as an indication of explosive behavior and should not be considered as rigid limits. The development of economical chemical processes involving acetylene at elevated pressures or under other hazardous conditions calls for decomposition tests for the crucial stages where decomposition could occur. This must be done in close cooperation with official testing institutions, such as the Bundesanstalt für Materialprüfung (BAM) in Germany.

In general, the following rules should be observed in handling acetylene:

- Temperature and pressure must be selected so as to avoid liquefaction of acetylene.
- Reactions of acetylene in solvents or with liquid reaction components must be carried out at such acetylene concentrations that explosive decomposition of the acetylene in the liquid phase cannot occur. In many cases this condition is fulfilled at an acetylene loading below 100 m^3 (STP) per cubic meter of solvent. Higher loadings are only permitted if additional precautions are taken, such as filling the volumes containing the liquid with

steel packings. The formation of a separate gas phase has to be avoided.

– The technical rules (such as *TRAC* [97]) are valid for pure gaseous acetylene. If an inert gas, such as nitrogen, is added to the acetylene, higher acetylene partial pressures are permitted.
– In the design of apparatus the partial pressure of acetylene should be selected so that the minimum distance to the decomposition limit is about 20 %. The apparatus should be designed to withstand pressures (1) 12-fold the initial pressure for pure acetylene systems or (2) the initial pressure plus 12-fold the acetylene partial pressure for mixtures and solutions.
– Formation of hydrates (see Chap. 2) under pressure must be avoided because this leads to obstructions in the apparatus and pipelines. The melting point of these compounds is in the range 0 –13 °C; therefore, pressurized acetylene containing water has to be kept above 15 °C.

In addition to the measures for building construction, electrical installations, fire protection, purging, and leak detection, acetylene plants and distribution systems are provided with flame traps and flashback and release valves and locks [98, 99]. Flame traps consist either of tubes immersed into water-filled cylinders (wet trap) or cylinders filled with a packing of high surface area to decelerate the decomposition. A wet arrester, which is used for an acetylene distributing line, is shown in Figure 41. Suitable materials for dry-trap packings are sinter metals, ceramic beads (e.g., Raschig rings), bundles of small tubes, and corrugated metal foils [100, 101].

Tapping points for acetylene distribution units which meet the German *TRAC* rules include a nonreturn valve to avoid intrusion of air from downstream, a sinter-metal flame trap, and a thermo- or pressure-sensitive spring lock. The last closes if a flame is stopped by the trap but still burns outside of the flame trap. Detailed information is given in [98].

Transportation in Pipelines. Acetylene is occasionally transported in pipelines. Figure 42 shows the safety components of an acetylene pipeline between Burghausen and Gendorf, Federal Republic of Germany. The pipeline was operated until 1976 without incident. Its length is 8 km, and the pipes are 300 mm in diameter. Design pressure was 100 bar, although operation pressure was only 2 bar at the inlet and 1.25 bar at the outlet. The pipeline was provided with rupture disks, which open to atmosphere in case of decomposition. Quick closing valves are initiated simultaneously to protect both upstream and downstream equipment. At each end, part of the pipeline is filled with tube bundles to stop propagation of any acetylene decomposition. The flame traps consist of 600-mm-diameter U's filled with Raschig rings.

Figure 41. Hydraulic flame trap for acetylene lines (Union Carbide), [102]

Figure 42. The 8 km acetylene pipeline from the Marathon refinery, Burghausen, to Farbwerke Hoechst, Gendorf, Federal Republic of Germany [103]

A report [102] is available on an acetylene-decomposition event in a pipeline system, which demonstrates the need for safety measures. Instead of transportation of pure acetylene, pipeline transportation of acetylene solutions in acetone was proposed as safer [103]. In the United States, transportation of acetylene solutions in liquid ammonia was considered for existing ammonia distribution systems [104].

Hazardous Acetylene Traces in Low-Temperature Processes. Acetylene is the most dangerous component in gas mixtures processed in low-temperature plants. In air separators, for example, acetylene can be suspended in liquid oxygen as a solid or as a segregated liquid phase that is quite unstable and tends to uncontrollable and violent decomposition. (The solubility of acetylene in liquid oxygen is low, see Chap. 2) Therefore much attention must be given to checking for and removing acetylene in low-temperature separation plants.

Normally air contains some acetylene, up to 0.3 mL/m^3. In industrial areas, especially in the proximity of petrochemical plants, higher concentrations (up to 1 mL/m^3) can occur. Without any measures, acetylene in the feed air of an air separator would be enriched in the cold section of the unit.

In modern air separators alternating molecular sieve adsorbers are used. The adsorbers obey the following breakthrough sequence:

$$CH_4 - C_2H_6 - \begin{matrix} C_2H_4 \\ CO_2 \\ C_3H_8 \end{matrix} - C_2H_2 - C_3H_6 - C_4 - H_2O$$

To avoid acetylene breakthrough the adsorber is operated for sufficient CO_2 removal and is regenerated when the CO_2 concentration at the adsorber outlet starts to increase. Further details are given in [105 – 109].

Another possible way to remove acetylene and other combustible air contaminants is catalytic oxidation prior to the separation [107, 110]. This method, being expensive, is rarely used.

All air separators are provided with routine analysis systems for acetylene (→ Oxygen). Routine analysis concentrates on the liquid oxygen of the main condenser [111].

The removal of acetylene in cracked gas separation is treated in Section 4.4.2. The processing of other acetylene-containing gases, e.g., coke-oven gas, by low-temperature separation is described in [112].

5.2. Acetylene Storage in Cylinders

Because of its tendency to deflagrate or to detonate, acetylene cannot be compressed and stored in gas cylinders like other gases. At the end of the 19th century attempts to store acetylene under high pressure or liquefied led to fatal detonations in the USA, Paris, and Berlin.

For desensitizing, acetylene stored in gas cylinders is dissolved in a solvent in which the acetylene is very soluble. This solvent is dispersed in a porous solid that completely fills the gas cylinder. As well as giving better solvent distribution the porous material arrests any local acetylene decomposition induced, for instance, by flashback.

Figure 43. Total pressure of acetylene solution in acetone as a function of acetylene : acetone ratio and temperature [7]

Acetone and dimethylformamide are the preferred solvents for acetylene in cylinders. An advantage of dimethylformamide is its lower vapor pressure, resulting in lower solvent losses during acetylene discharge. A disadvantage is its higher toxicity. The total pressure of an acetone-containing acetylene cylinder depends

on the acetylene : acetone ratio and on temperature as is shown in Figure 43. Deviations from the plotted curves resulting in higher pressures are caused by the porous filling of the gas cylinder, which absorbs acetone, changing the effective acetylene : acetone ratio [113].

Impurities in the acetylene decrease the dissolving capacity of the acetone. Figure 44 shows the effect of moisture on acetylene solubility. As a result, acetylene produced from calcium carbide and water has to be dried.

Figure 44. Solubility of acetylene in water-containing acetone at 25 °C and $p_{C_2H_2} = 1$ bar (0.1 MPa) [114]

Calcium carbide-based acetylene contains further impurities that have to be scrubbed out to avoid decreased solubility in acetone. Examples are divinyl sulfide and phosphine: 1 wt % divinyl sulfide in the acetone reduces the acetylene solubility from 35 g/kg to 31 g/kg at 20 °C and an acetylene pressure of 0.1 MPa. Further values, also for phosphine, are given in [114, 115]. The impurities have to be scrubbed out to residual concentrations of 0.5 g of phosphorus and 0.1 g of sulfur per cubic meter of acetylene.

During acetylene production from calcium carbide, disperse calcium hydroxide (0.1 – 1.0 μm) is produced. This contaminates the product gas. The calcium hydroxide present in acetylene filled into acetone-containing gas cylinders catalyzes aldol condensation of the solvent and reduces the solubility for acetylene:

$$2\ (CH_3)_2CO \rightarrow (CH_3)_2COHCH_2COCH_3$$

diacetonealcohol

Therefore, the solids content of calcium carbide-based acetylene for filling acetone-containing gas cylinders must be kept below 0.1 mg/m^3 [114, 116].

The gas cylinders have to be filled with definite amounts of acetylene and solvent. Commercial-grade, seamless gas cylinders which meet specified standards (in Germany, DIN 4664) may be filled with the amounts listed in Table 15.

The amounts are fixed by regulations for handling pressurized gases [118]. Corresponding regulations in the United States have been issued by the Department of Transportation [119].

To determine maximum acetylene filling of gas cylinders, extensive ignition, impact, and heating tests have been worked out [120, 121].

Figure 45. Porous silica material Linde M1 for acetylene cylinders (magnification 1 : 10000)

The porous material in the acetylene gas cylinders must satisfy the following requirements: no interaction with the cylinder material, acetylene, or acetone and suitable mechanical properties, such as sufficient impact resistance. Suitable materials include pumiceous compounds, silica, charcoal, asbestos fiber, and

alkaline carbonates. The porosity of these materials varies between 70 and 80 % [114, 122]. Modern monolithic materials are made preferably from silica, lime, and glass fiber. The mixtures are suspended in water to obtain a pasty material which is filled into the gas cylinders. The material is hardened at about 200 °C and subsequently dried and activated at 350 – 400 °C. A porosity of about 90 % is obtained.

Any porous material to be used for acetylene cylinders has to be examined and approved by competent authorities. The examination includes the determination of the maximum acetylene and solvent filling, the maximum filling pressure, and ignition and impact testing. Table 16 lists three porous materials approved for use in Germany. Figure 45 shows a photograph of "Linde M1" magnified 1 : 10000, clearly revealing the porous structure of such materials.

Methods for examining the materials have been standardized by CPI (Commission Permanente Internat. de l'Acétylène, de la Soudure Autogène et des Industries qui s'y rattachent, Paris) and ISO (International Organization for Standardization) [122].

Discharging acetylene from a gas cylinder leads to acetone losses because the partial pressure of acetone at 15 °C ranges from 0.14 bar at 15 bar total pressure to 0.18 bar at 1 bar total pressure. Solvent loss has to be replaced when an acetylene cylinder is reloaded. Further details concerning acetylene cylinders, porous materials, and valves can be found in [131].

6. Uses and Economic Aspects

6.1. Use in Metal Processing

Acetylene has many applications in the processing of metals and other materials. This is because of the high flame temperature and propagation velocity resulting in high energy densities and rapid heat transfer to the piece being worked. Examinations at Linde showed that for extreme oblique sections the efficiency using acetylene is up to 50 % higher than using propane as fuel gas [133]. The properties of an oxyacetylene flame given here supplement those in Section 5.1.

The temperature profile of an oxyacetylene flame consists of a hotter primary flame and a scattered secondary flame. The highest flame temperature is at the tip of the primary flame (Fig. 46). For material processing the primary flame is the more important.

Figure 46. Temperature profile of an oxyacetylene flame

The heating efficiency of the primary flame is the product of the volume-based heat released by the primary flame and the propagation velocity. This is plotted in Figure 47 for the oxyacetylene flame and some other flames. The heat transferred in welding is generated by radiation, convection, and thermal conduction (see Table 17). The heat transfer is promoted by a high temperature gradient between flame and workpiece.

Figure 47. Heating efficiency of acetylene–oxygen mixtures and mixtures of other hydrocarbons with oxygen
* based on area of primary flame cone

Oxidizing, neutral, or reducing (carburizing) flames can be obtained by varying the oxygen : acetylene ratio (Fig. 40). For steel, alumina, and copper welding usually neutral or slightly reducing flames are used, whereas oxidizing flames are preferred for brass welding, cutting, pickling, and surface hardening [124]. Acetylene is burned with oxygen in single torches or in bundles of torches, the chief components of which are the connections for acetylene and oxygen, regulating valves, a mixing chamber (usually of the injection type), a flashback protection element, and a nozzle adapted to the specific applications [125, 126].

Oxyacetylene flames are used in welding, cutting, brazing, soldering, surfacing, flame spraying, heating, hardening, straightening, cleaning, pickling, rust removal, and decarbonizing.

Acetylene–air flames are occasionally used for tin brazing, hot air welding of thermoplastics, glassworking, and paint removal [125], although the convenience and safety of fuels such as propane or butane has displaced acetylene in those applications. Soft and hard soldering, flame hardening, and flame tempering are important applications for the softer acetylene–air flame. For acetylene–air mixtures, self-aspirating Bunsen-type and acetylene–compressed air burners are used.

The different uses of oxyacetylene and acetylene–air flames in metal working, the procedures, and the equipment are comprehensively described in [7] and [127]; other sources of information for oxyacetylene flame properties in welding are [123, 124], and [128].

6.2. Use as Raw Material in Chemical Industry

Because of the diversity of acetylene chemistry (see Section 3.1), acetylene has been used as a starting material for a great variety of industrially important products. These are summarized, together with their applications, in Figure 48.

Between 1960 and 1970, when worldwide acetylene production peaked, most of the products listed in Figure 48 were produced via acetylene. The competition between acetylene and the olefins since the 1970s (see Section 6.3) has resulted in substitution of ethylene and propene for acetylene, especially in the production of acetaldehyde and acrylonitrile. At present, acetylene is used mainly for the production of vinyl chloride, vinyl acetate, and other vinyl esters; acrylic acid; acetylene black; and acetylenic chemicals such as 1,4-butynediol and acetylenic alcohols. For the acetylenic chemicals the acetylene route is either the only commercial production process available or the predominant process. Vinyl chloride, vinyl acetate, and acrylic acid, formerly the main products from acetylene, are pro-

duced today mainly from ethylene and propene [3].

6.3. Competitive Position of Acetylene as Chemical Feedstock

Today, acetylene plays an important role only in the production of the acetylenic chemicals. The fact that acetylene production has not decreased further seems to indicate that the competition from the olefins is no longer as strong as it was. The main reason for this is that European olefin chemistry depends on refinery products, which have become more expensive than natural gas, the main feedstock for acetylene. Another contributing factor is that acetylene is produced only in old plants, which have low capital costs.

In addition, process improvements, such as an increase in thermal efficiency and optimum use of byproducts by other plants, can make acetylene more competitive. The position of acetylene in chemical industry may be advanced because of the variety of valuable products to which it can be converted in high yields with known technology. Acetylene must compete with ethylene for the production of vinyl chloride and vinyl acetate, and for the production of acrylic acid and its esters it must compete with propene. The Stanford Research Institute [3] has investigated this question in detail. The results, which take into account both capital investment (25 % return) and specific consumption figures for the various processes, show that the prices at which

Figure 49. Acetylene–methanol plant

the alternate routes are competitive can be expressed by the following equations:

for vinyl chloride $A = 1.10\ E + 0.42$
for vinyl acetate $A = 1.23\ E + 0.40$
for acrylic acid $A = 1.74\ P + 0.23$

where A is the acetylene price, E is the ethylene price, and P is the propene price, all in \$/kg. For example, if ethylene costs 0.65 \$/kg, acetylene can cost 1.15 \$/kg for the production of vinyl chloride and 1.21 \$/kg for the production of vinyl acetate. If propene costs 0.49 \$/kg, acrylic acid can be profitably produced from acetylene if it costs 1.08 \$/kg or less.

Acetylene prices of 1.08 to 1.21 \$/kg or less can be reached in a new plant only with optimal integration of energy and byproducts within an integrated chemical plant. Figure 49 shows the flow sheet of a 100 000 t/a gas-based partial oxidation acetylene plant in a chemical complex. The required oxygen facility and methanol plant based on acetylene synthesis gas (off-gas) are included. The main products of the complex are acetylene and methanol. The acetylene process is operated with improved quenching technology, allowing a high proportion of energy to be regained in the form of steam. The aromatic residue oil from a steam cracker is converted into high-purity coke and light aromatics.

A production cost estimate based on power, feedstock, and product prices roughly corresponding to market prices in 1982 shows that low production costs for acetylene are possible under the conditions described, in spite of the relatively high natural gas price of 5.5 \$/10^6 BTU (0.021 \$/kW h), which in heating value terms comes very close to that of crude oil (0.022 \$/kW h). The difference in production costs between acetylene from natural gas and ethylene from naphtha (price 333 \$/t, corresponding to 0.028 \$/kW h) is so slight that acetylene from new plants can once again compete with ethylene for certain syntheses, provided that there is a difference between the costs of natural gas and naphtha. This was nearly 0.007 \$/kW h in 1982 in Germany. A similar calculation for the acetylene production by the Hüls arc process based on an ethylene price of 600 \$/t and a hydrogen price 40 % above the heating value results in the same acetylene product value at 0.038 \$/kW h for electrical power. Lower electrical energy costs favor the arc process.

7. Propyne

Propyne [*74-99-7*], methylacetylene, is obtained in cracking processes mostly as a byproduct together with its isomer propadiene [*463-49-0*], allene. Typical concentrations depend on the feedstock and the cracking conditions (Table 10) and vary between 0.3 and 0.8 wt %. The corresponding figures for propadiene are 0.3 – 0.6 wt %.

Figure 50. Vapor pressure curves of propyne and propadiene [129]

Figure 51. Solubility of propyne in various solvents at infinite dilution
a) Water; b) Methanol; c) *N*-methylpyrrolidone; d) DMF

Pure propyne is a colorless, nontoxic, flammable gas. The important physical properties of propyne are listed in Table 18 [5, 6, 129]. Vapor pressure curves of propyne and propadiene including melting and critical points are shown in Figure 50 [129]. Table 19 summarizes solubility coefficients of propyne for various solvents [9]; further data are available in [10]. The solubility of propyne in various solvents is shown in Figure 51; the solubilities of the C_3 hydrocarbons in DMF are plotted in Figure 52 for infinite dilution.

Figure 52. Solubility of the C_3 hydrocarbons in DMF at infinite dilution
a) Propyne; b) Propadiene; c) Propene; d) Propane

The equilibrium between the two isomers of C_3H_4 is reached in the presence of catalysts (for example $Al_2O_3/_3$, SiO_2, activated carbon, and γ-Al_2O_3/Na_2CO_3) [130, 131]. At 270 °C the equilibrium mixture contains 82 % propyne, and at 5 °C, 91.1 % propyne. For calculated data, see [132]. This equilibrium is important for the industrial propyne recovery process.

The decomposition pressure as a function of the ignition energy for propyne (and propadiene) is plotted in Figure 38. The lower and upper flammability limits of propyne in air are about 2.3 and 16.8 vol %. For propadiene only ranges are available: 1.7 – 2.5 and 12 – 17 vol % [133].

Production. Propyne and propadiene can be recovered from cracked gas by solvent extrac-

Figure 53. Propyne recovery process (Linde, Shell [77])
MA: methylacetylene; PD: propadiene

tion. The process is outlined in Figure 53 [79, 134] and is similar to the recovery of acetylene (see Chap. 4.4.2). This process was developed by Linde and Shell and is ready for use [70]. Nevertheless, until today (2006) it has not been used in an industrial application. An important step is the catalytic isomerization of propadiene to propyne in the liquid phase on a catalyst [131].

The bottom product from the propene/propane splitter is routed to depropanizer II for removal of traces of C_{4+} hydrocarbons originating from the feed and the isomerization reactor effluent. The overhead is sent to the absorption column. The propane (and some propene) is routed back to the cracking furnace. Propyne (MA) and propadiene (PD) are stripped off in the corresponding columns. The propadiene fraction is converted to propyne in the isomerization reactor and recycled to the feed. Traces of solvent in the pure propyne are removed by cooling. The product can be sent directly to methyl methacrylate (MMA) unit, where MMA is manufactured by reaction of propyne with carbon monoxide and an alcohol in the presence of a Pd-based carboxylation catalyst [131, 135].

Usually propyne and propadiene are undesirable byproducts of the steam cracking process. The crude C_3 fraction can contain up to 6 mol % MAPD, whereas the MAPD content of chemical-grade propene typically has to be $<$ 20 ppm and that of polymerization-grade propene $<$ 2 ppm. To this end MA and PD are removed by selective hydrogenation in the liquid or gas phase. Typical conditions are pressures of 1.5 – 5 MPa and inlet temperatures of 20 – 100 °C. The vapor-phase processes are declining in

importance. Today mainly liquid or composite phase are in use as they have some advantages:

- Operation at lower temperatures (higher selectivity)
- Lower operating costs (no vaporization of the feed and recondensation of the product)
- Regeneration of reactor in situ (removal of polymers)
- Lower frequency of catalyst regeneration
- For high concentration of C_3H_4 in the feed, two reactors are often sufficient; the gas-phase process requires more reactors
- Control of conversion by injection of hydrogen (no excess hydrogen) reduces investment cost
- Control of temperature by use of vaporization minimizes risk of runaway

Table 18. Physical properties of propyne [5, 6, 129]

Molecular mass	40.065
Critical temperature	402.39 K (129.24 °C)
Critical pressure	5.626 MPa
Critical volume	0.1635 m^3/kmol

Surface tension *	1.47×10^{-2} N/m (273.15 K)

* Predicted or estimated.

As in the case of acetylene hydrogenation, Pd catalysts are used. Several catalyst manufacturers offer special catalysts for C_3 hydrogenation. The selectivity in case of liquid-phase hydrogenation to propene is about 60 – 70 % and depends on the concentration of C_3H_4 in the C_3 feed. For better control of reaction heat, some product is normally recycled to the feed. The cycle time of the catalyst is very sensitive to contaminants (and to byproduct formation in gas-phase processes), especially in the first reactor. A reactivation procedure is necessary when the catalyst loses its activity. In contrast to acetylene hydrogenation, the requirements on MAPD hydrogenation are not that strict. MAPD going to the propane - propylene separation (C_3 splitter) mainly ends up in the bottom product propane which is usually recycled to the cracking furnaces. This means that there is another purification step, which can remove MAPD from the propene product. As propyne and propadiene are different chemical compounds they are hydrogenated with different reaction rates. In contrast, many reports in literature about hydrogenation only consider a simplified model with a combined MAPD fraction and do not discriminate between both isomers.

Stabilized Propyne–Propadiene Mixtures. As a replacement for acetylene, stabilized propyne–propadiene mixtures are available commercially. Trade names are Tetrene or MAPP gas. These mixtures are stabilized by propane, propene, and/or butane and are used for metal cutting, welding, hardening, and brazing. The flame properties are closer to those of propane–propene mixtures. Therefore stabilized C_3H_4 mixtures have not yet won a large-scale market. Further information is available in [136]. In Europe, those mixtures are available only very rarely. In Europe, mixtures with the trade name MAPP gas have a rather low MAPD content actually and mainly consist of propene, propane, and butane. Only in the US the original MAPP mixture has some importance.

8. Toxicology and Occupational Health

Pure acetylene is a simple asphyxiant. When generated from calcium carbide, acetylene is frequently contaminated with arsine, hydrogen sulfide, or phosphine, and exposure to this impure acetylene has often resulted in serious consequences. Commercial acetylene no longer contains these impurities and is therefore less harmful [137].

The lowest published lethal concentration for rats is 9 vol % [138]. Dogs are less sensitive: 80

vol % acetylene in the air is necessary to produce a narcosis accompanied by an increased blood pressure and a decreased pulse frequency (stimulation of vasomotor and vagus centers) [139]. In humans, the inhalation of air containing 10 vol % acetylene has a slight intoxicating effect, marked intoxication occurs at 20 vol %, incoordination at 30 vol %, and unconsciousness within 5 min on exposure to 35 vol %. Inhaling 35 vol. % for 5 – 10 min or 10 vol % for 30 – 60 min is lethal. Symptoms of intoxication are excitement, coma, cyanosis, weak and irregular pulse, and memory failure [140 – 142].

There is no evidence that *repeated exposure* to tolerable levels of acetylene has effects deleterious to health [143]. Inhalation of air with 33 vol % of acetylene by humans led to unconsciousness within 6 min, but when the experiment was repeated within the week the susceptibility to acetylene decreased: 9 min were required on the second exposure and more than 33 min on the third exposure to produce unconsciousness [139].

Acetylene does not irritate the mucous membranes [137]. Neither threshold limit value (TLV) nor a MAK has been established. The standard air concentration allowed for OSHA and NIOSH is 2500 ppm [141].

HARTMUT HÖKE, Weinheim, Federal Republic of Germany

1. Physical Properties 1
2. Chemical Properties 1
3. Production 1
4. Uses 1
5. Toxicology 2
6. References 2

Acridine [*260-94-6*], $C_{13}H_9N$, was discovered in coal-tar anthracene oil by C. GRAEBE and H. CARO in 1870, and identified as dibenzopyridine by C. RIEDEL, A. BERNTHSEN, and F. BENDER in 1883.

1. Physical Properties

M_r 179.22, *mp* 110 °C, *bp* 345 °C (at 1013 hPa), ϱ at 20 °C 1.1005 g/cm^3. Colorless needles or prisms; volatile in steam; slightly soluble in boiling water, readily soluble in organic solvents such as alcohol, ether, carbon disulfide, and benzene; solutions show blue fluorescence.

2. Chemical Properties

Acridine is a weak tertiary base. With strong acids, it forms crystalline, yellow salts that decompose readily in boiling water. Acridine is stable when heated with concentrated alkali or hydrochloric acid. Nitration with nitric acid yields mainly 2- and 4-nitroacridine and small amounts of dinitroacridines. Reduction gives acridane (9,10-dihydroacridine [*92-81-9*]) preferentially. Oxidation results in the formation of acridinic acid (quinoline-2,3-dicarboxylic acid [*643-38-9*]) or acridone, depending on the oxidizing agent used. Acridine forms quaternary acridinium salts with alkyl or aryl halides and sulfates.

3. Production

Acridine can be separated as sodium acridone sulfonate from the coal-tar anthracene oil boiling between 300 and 360 °C (→ Tar and Pitch) by extraction with dilute sulfuric acid [5] or with aqueous sodium bisulfite. The free base is obtained by decomposition of the salt with caustic soda [6]. Acridine can be synthesized by reduction of acridone or 9-chloroacridine.

Acridone [*578-95-0*], pale yellow needles,

Acridone

mp 354 °C, is obtained by the cyclization of diphenylamine-2-carboxylic acid (phenylanthranilic acid), which is synthesized from aniline and 2-chlorobenzoic acid. *9-Chloroacridine* [*1207-69-8*], almost colorless crystals, *mp* 120 °C, is obtained by reacting phosphoryl chloride with diphenylamine-2-carboxylic acid.

4. Uses

Acridine as such has no commercial significance. In the patent literature it is proposed as an antioxidant, as a polymerization and corrosion inhibitor, as an additive to peroxidic vulcanizing agents for ethylene – propylene rubber, as a thermal stabilizer for polyolefins, and also as an occult blood test reagent, used in paper strips for blood tests. The acridine dyes are made from other starting materials (→ Triarylmethane and Diarylmethane Dyes, Chap. 8.).

10.1002/14356007.a01_147

5. Toxicology

Animal studies have shown that acridine is slightly toxic: the LD_{50} value is about 2000 mg/kg (rat, oral) [7], [8]. Industrial observations show that exposure to acridine dust or vapor causes strong irritations of the skin and mucous membranes combined with sneezing, with itching or even inflammation of the skin. Some acridine derivatives cause sensitization of the skin, especially on exposure to light. Exposure limits at the workplace (MAK, TLV) are not specified. Resorptive intoxication is unknown.

Acrolein is the simplest unsaturated aldehyde. It is an important intermediate in the production processes of a variety of substances. The main use of isolated acrolein is in the production of D,L-methionin, but in far more production processes, acrolein is used without purification. Acrolein is an extremely reactive chemical and, in very low concentrations, acts as a very effective broad-spectrum biocide. Methacrolein is produced commercially as an organic intermediate, which is used as building block for chain expansions or, in limited application, in the synthesis of flavors and fragrances.

1. Introduction

Acrolein [*107-02-8*], propenal, acrylaldehyde, CH_2 =CH-CHO, the simplest unsaturated aldehyde, is a colorless, volatile, toxic, and lacrimatory liquid with a powerful odor.

Acrolein (Latin: acer - acrid, oleum = oil) was discovered 1843 by Redtenbacher in overheated fat [1].

The commercial production of acrolein by heterogeneously catalyzed gas-phase condensation of acetaldehyde and formaldehyde was established by Degussa in 1942. Today, acrolein is produced on a large commercial scale by heterogeneously catalyzed gas-phase oxidation of propene.

Acrolein is an important intermediate for numerous substances (see Chap. 6). The main use of commercial, isolated acrolein is the production of D,L-methionine [2], an essential amino acid used as an animal feed supplement. In the production of acrylic acid, acrolein is not isolated from the gas-phase reaction mixture but is oxidized further on a heterogeneous catalyst. The produced amount of nonisolated acrolein exceeds the amount of isolated acrolein by far. Less important is the production of special chemicals from acrolein.

Several review articles [3 – 9] (see also [92]) and a monograph [10] describe the preparation, reactions, and uses of acrolein.

Methacrolein [*78-85-3*], 2-methylpropenal, α-methylacrolein, CH_2=C(CH_3)-CHO, is a colorless, volatile, toxic, and lacrimatory liquid with a piercing odor. It is an intermediate in one of the processes for the production of methyl methacrylate (see Section 3.2).

2. Properties

2.1. Physical Properties

The important physical properties of acrolein and methacrolein are compiled in Table 1. The solubility of acrolein in water is limited. It is soluble in many organic solvents, such as alcohols, ethers, and aliphatic or aromatic hydrocarbons. Methacrolein has properties similar to acrolein but is less soluble in water.

Table 1. Physical properties of acrolein and methacrolein

	Acrolein	Methacrolein
M_r	56.06	70.09

2.2. Chemical Properties

Acrolein is an extremely reactive chemical because of its conjugated vinyl and aldehyde groups. It undergoes reactions characteristic of both an unsaturated compound and an aldehyde. The conjugation between the carbon – carbon double bond and the carbonyl group increases the reactivity of both groups, which can react either together or separately [9]. Highly exothermic polymerization can occur spontaneously (see Chap. 5).

Diels – Alder Reaction. Acrolein reacts as both a diene and a dienophile. Thus two molecules of acrolein can form a cyclic dimer, 3,4-dihydro-2*H*-pyran-2-carboxaldehyde [*100-73-2*] [11]:

The dimer is formed by the uncatalyzed, thermal reaction of acrolein at approximately 190 °C (1 h for 75 % acrolein conversion) together with polymeric side products. Sufficient stabilization with hydroquinone or complexing compounds, such as polyvalent organic acids [13], is necessary for high yields. This "thermal dimer" is a clear liquid with an unpleasant odor: *bp* 151.3 °C at 101.3 kPa, d_{20}^{20}1.0775. Acid hydrolysis of the dimer yields 2-hydroxyadipaldehyde [*141-31-1*], which can be hydrogenated to form 1,2,6-hexanetriol [*106-69-4*].

Acrolein behaves as a 1,3-diene in reactions with dienophiles in which the electron density of the carbon-carbon double bond is increased by electron-releasing substituents. Vinyl ethers [10, 12, 14, 15] and vinylamines [16] react readily with acrolein to form dihydropyrans. The reaction of methyl vinyl ether and acrolein to form 3,4-dihydro-2-methoxy-2*H*-pyran [*4454-05-1*] is a commercially important example. At a reaction temperature of 160 – 190 °C, reported yields are 80 – 90 % [12].

Acid hydrolysis of this product leads to glutaraldehyde [*111-30-8*] (for uses, see page 11).

The electron-deficient vinyl group of acrolein reacts readily with conjugated dienes, such as butadiene or substituted butadienes, forming

derivatives of 3-cyclohexene-1-carbaldehyde [14, 17]:

3-Cyclohexene-1-carbaldehyde (1,2,3,6-tetrahydrobenzaldehyde) [*100-50-5*] is formed at 100 – 150 °C in ca. 80 – 90 % yield and is a valuable intermediate for various commercial products. With pentaerythritol a cyclic acetal is formed, which can be used as a stabilizer against ozone degradation in natural or synthetic rubber [18]:

The carbaldehyde also is used for the synthesis of cycloaliphatic epoxides, such as the following:

Addition to the Carbon – Carbon Double Bond. The β-carbon atom of acrolein, which is polarized by the carbonyl group, behaves as an electrophile. Therefore nucleophilic reagents, such as alcohols, thiols, water, amines, active methylene compounds, and inorganic and organic acids, add to the carbon – carbon double bond of acrolein in the presence of acidic or basic catalysts. These reactions must be carried out under carefully controlled conditions in order to minimize undesirable side reactions [10].

The addition of water under mild acidic conditions gives 3-hydroxypropionaldehyde (HPA) [*2134-29-4*] with high selectivity. Buffer solutions with a pH of 4 – 5 [23, 24] or weak acidic ion-exchange resins [25] are preferentially used as catalysts. Further hydrogenation of the aqueous solutions gives 1,3-propanediol [*504-63-2*] [26, 27]. Direct oxidation of aqueous solutions of 3-hydroxypropionaldehyde at pH 3 with precious metal catalysts produces 3-hydroxypropionic acid [28]. If the oxidation is conducted at above pH 7, the malonate anion is formed in high yield [29].

Acrolein reacts rapidly with hydrogen chloride or hydrogen bromide to form 3-chloropropionaldehyde [*19434-65-2*] [30, 31] or 3-bromopropionaldehyde, but these products easily polymerize, e.g., to trimers and tetramers, in the presence of acids. The preferred procedure for making 3-halopropionaldehyde acetals is therefore simultaneous hydrogen halide addition and acetalization. Acetal yields are about 90 % [31, 32].

Chlorine and bromine add to acrolein in dilute aqueous solution to give 2,3-dihalopropionaldehydes with about 85 % yields; these products can be dehydrohalogenated to form the 2-haloacroleins [33].

These 2-haloacroleins are considered to be potent mutagens [34]. Further halogenation of the 2-haloacroleins provides the 2,2,3-trihalopropionaldehydes, which are valuable intermediates in the synthesis of folic acid [35] (→ Vitamins).

The addition of hydrogen sulfide to two equivalents of acrolein followed by an aldol reaction forms 3-formyl-5,6-dihydrothiopyran [*30058-79-8*] [36].

The base-catalyzed addition of methanethiol to form 3-(methylthio)propionaldehyde [*3268-49-3*] is the commercially most important reaction used in the synthesis of the essential amino acid D,L-methionine (→ Amino Acids, [2]).

Reactions of the Aldehyde Group. The selectivity of the acid-catalyzed *acetalization* strongly depends both on the nature of the alco-

hol used and on the catalysts [10]. The most important side reactions yield the corresponding 3-alkoxypropionaldehydes and 3-alkoxypropionaldehyde acetals.

Usually cyclic acetals are formed much more easily, especially with branched diols such as 2-methyl-1,3-propanediol, than the acyclic acetals of lower alcohols [37, 38]. For the preparation of various cyclic acetals, several continuous processes are known [39]. High yields (more than 90 %) of the dimethyl and diethyl acetals can be realized by means of special processes in combination with extraction [40].

Acrolein acetals are valuable intermediates. They have gained interest in the last years as safer forms for the transport of acrolein, especially 2-vinyl-1,3-dioxolane [*3984-22-3*]. The acetals can be cleaved back into acrolein easily in aqueous acidic solutions [41]. These solutions are of particular interest for the use of acrolein as an aquatic herbicide and as a hydrogen sulfide scavenger in oil-field waters.

One of the most interesting cyclic acetals is the spiro diacetal, diallylidene pentaerythritol [*78-19-3*], prepared by condensing pentaerythritol with two moles of acrolein. It can be polymerized with vinyl or other monomers to form spirane resins [42].

The hydroformylation of acrolein acetals, especially cyclic acetals, leads to the monoacetals of 1,4-butanedial. Subsequent hydrolysis and hydrogenation of this hydroformylation product produces 1,4-butanediol [37, 43].

A synthesis of D,L-tryptophan from 1,4-butanedial has been described [44]

Acrolein diacetate [*869-29-4*] 2-propene-1,1-diol, diacetate, is easily prepared in 90 % yield by the acid-catalyzed reaction of acetic anhydride with acrolein [10]:

Hydrogen cyanide addition in the presence of mild alkaline catalysts gives acrolein cyanohydrin [*5809-59-6*] in yields of more than 90 % [10, 45, 46]. Acrolein cyanohydrin is a vesicant; it decomposes vigorously in the presence of alkali and is stabilized by traces of acid. Its reaction with acetic anhydride yields acrolein cyanohydrin acetate, which is a valuable intermediate in the synthesis of pharmaceutically and biologically active substances [47 – 49].

Simultaneous Reaction of the Aldehyde and Vinyl Groups. Acrolein has long been recognized as an intermediate in the Skraup synthesis of quinolines from aromatic amines and glycerol [10]. However, little commercial use has been made of acrolein or methacrolein as starting materials for this reaction.

The heterogeneously catalyzed gas-phase condensation of acrolein and ammonia over multicomponent Al_2O_3 or $SiO_2 - Al_2O_3$ catalysts gives 45 % 3-methylpyridine [*108-99-6*] with 20 – 25 % pyridine [*110-86-1*] as a byproduct [10, 50 – 52].

This reaction, usually carried out in a fluidized-bed reactor, has been generalized to a universal synthesis for substituted pyridines [52] (→ Pyridine and Pyridine Derivatives).

Isocyanuric acid reacts with acrolein to form an adduct useful as a cross-linking agent [53].

The bifunctional reactivity of acrolein also has been used in various syntheses of heterocycles [54]. Examples include the reactions with phenols, yielding substituted chromenes or chromanes [55], and the reaction with 2-aminophenols to produce 8-quinolinols [56]. The reaction of acrolein with excess phenol under acidic conditions leads to a mixture of polyphenols with 1,1,3-tris(4-hydroxyphenyl)propane [*4137-11-5*] as the main product [57].

Further reaction with epichlorohydrin leads to glycidyl polyphenols which are useful as epoxy hardeners [58]. Reaction with glycidyl methacrylate followed by polymerization gives heat-resistant materials with high impact resistance [57].

The reaction of acrolein with urea leads to (hexahydro-2-oxo-4-pyrimidinyl urea) [*31036-27-8*], which has been proposed as a fertilizer [10, 59]:

The condensation of acrolein with hydrazine and substituted hydrazines gives pyrazolines in 80 % yield [60, 61]:

Acrolein reacts with formaldehyde under alkaline conditions to give pentaerythritol [*115-77-5*] [62]. Yields are lower than in the commercial synthesis of pentaerythritol via acetaldehyde and formaldehyde.

Sodium bisulfite reacts with acrolein to form a stable adduct, the disodium salt of 1-hydroxypropane-1,3-disulfonic acid [*35850-94-3*]. This reaction can be conveniently applied for deodorization of spilled acrolein.

Reduction. The selective reduction of acrolein to allyl alcohol [*107-18-6*] in high yields (90 %) is accomplished by hydrogen transfer from secondary alcohols, such as 2-propanol, in a Meerwein – Ponndorf reaction in the liquid phase [10] or from ethanol or 2-propanol in the gas phase over magnesium oxide catalysts [63 – 65] or rare earth oxide catalysts [66] at 300 – 500 °C.

Moreover, the aldehyde group is selectively reduced by metal hydrides, such as sodium borohydride or lithium aluminum hydride [67]. The catalytic hydrogenation to allyl alcohol [63, 68] is either less selective or selective only at very low conversions.

Oxidation. Glycidaldehyde [*765-34-4*] is easily prepared in 80 – 90 % yield by reaction with aqueous hydrogen peroxide at pH 8 – 8.5 [69].

Hydration of the oxirane group gives an aqueous solution of D,L-glyceraldehyde [*56-82-6*] [70].

Acrolein is oxidized commercially with molecular oxygen to form acrylic acid (→ Acrylic Acid and Derivatives).

Polymerization. Acrolein readily polymerizes on heating, on exposure to light, or by the action of various initiators. The properties of the acrolein polymer depend on the polymerization conditions, such as the type of initiator, solvent, and reaction temperature [71].

The functional groups of acrolein (vinyl and aldehyde) can polymerize either separately or together. Radical-initiated polymerization takes place exclusively at the vinyl group, leading to polymers with aldehyde groups **1**, which very

easily yield tetrahydropyran structures **2**. Ionic polymerization gives rise mostly to polymers with vinyl groups **3** along with such polymers as **1** and **4**.

1

2

3

4

Radical polymers are infusible and insoluble in common solvents, whereas the products of anionic initiation are soluble in many organic solvents. In addition to homopolymers, copolymers with most vinylic and acrylic comonomers have been obtained. Furthermore, the carbonyl groups of polyacrolein (**1**) can be modified chemically under mild conditions. Most of the polyacrolein derivatives are soluble in organic solvents or even in water.

These polymers gained interest because of their biocidal activity [72, 73]. The biocidally active component is acrolein, which is slowly released from these polymers [73].

Photochemical (laser) method was used to synthesize ultrafine particles from gaseous mixtures of acrolein and some organosilicon compounds. The polyacrolein particles are in discussion to its applicability to nanotechnology [74].

3. Production

3.1. Acrolein by Propene Oxidation

The first process for acrolein production was commercialized by Degussa in 1942. It was based on the vapor-phase condensation of acetaldehyde and formaldehyde, catalyzed by sodium silicate on silica supports at 300 – 320 °C [75]. This method prevailed until 1959, when Shell began producing acrolein by the vapor-phase oxidation of propene over a cuprous oxide catalyst. The catalyst performance in this process was very poor. In 1957 Standard Oil of Ohio (Sohio) discovered the bismuth molybdate catalyst system, which yielded a fairly good selectivity but still a low propene conversion [76, 77].

$$CH_2 = CH{-}CH_3 + O_2 \rightarrow CH_2 = CH{-}CHO + H_2O$$
$$\Delta H = -340.8 \text{ kJ/mol}$$

The major byproducts of this reaction are acrylic acid and carbon oxides in addition to minor products such as acetaldehyde, acetic acid, formaldehyde, and polyacrolein.

Catalysts for the Oxidation of Propene. The discovery that propene could be oxidized rather selectively to acrolein over copper(I) oxide [78] marked the beginning of the current process of catalytic alkene oxidation to aldehydes over metal oxide catalysts [79]. However, low conversion of propene (20 %) per pass [80], significant recycle of unreacted propene, and low acrolein selectivities were reported for this catalyst. The propene oxidation gathered impetus with the discovery of the bismuth molybdate – bismuth phosphomolybdate system ($Bi_9PMo_{12}O_{52}$ on an SiO_2 support) in 1957 by Sohio [76, 77]. Bismuth -molybdenum oxides also are essential components of commercial catalysts [81 – 84]. The initial step is generally described as coordination of propene on a molybdenum site. Bismuth is involved in the rate-determining hydrogen abstraction from propene. [85]. The mechanism of the main oxidation reaction could be explained by the mechanism of Mars–van Krevelen [86]. The catalysis of propene oxidation to acrolein consists of two reaction cycles: a catalyst reduction cycle (selective product formation), and a catalyst reoxidation cycle (lattice-oxygen regeneration). Only the nucleophilic lattice oxygen (O^{2-}) of the catalyst forms selectively acrolein. In the case the adsorbed electrophilic oxygen reacts with propene, total oxidation to CO_x is favored. To balance the redox properties of the catalyst, additional metal oxides are used.

Modern catalysts are multicomponent metal oxide systems. Knapsack [87] first proposed a three- or four-component catalyst containing Mo-Bi-Fe oxides. Strictly speaking, the multicomponent system consists of different main phases of binary compounds such as α-$CoMoO_4$, β-$CoMoO_4$, $Fe_2(MoO_4)_3$, $Bi_2O_3{\cdot}MoO_3$, $Bi_2O_3{\cdot}2\ MoO_3$ and $Bi_2O_3{\cdot}3\ MoO_3$ [88, 89]. $CoMoO_4$ forms the structural framework of the catalyst covered with iron

molybdate and an overlying layer of bismuth molybdate [90]. It is believed that the active sites of the catalysts are interfaces between $Fe_2(MoO_4)_3$ and β-$CoMoO_4$. Bismuth molybdate is responsible for the selectivity of the catalyst [91].

The optimization of the multicomponent catalyst system [79, 92, 93], to obtain a more selective and also active system with a high space time yield, is still a challenge. The patent application listed in Table 2 of the chemical companies BASF, Nippon Shokubai, Nippon Kayaku, Sabic, or Mitsubishi are some representative examples. The performance of the catalyst could be improved by adding further metal oxides, e.g., of Co, Ni, P, Sb, W, or K and the optimization of the preparation technique. The data of various catalysts that are listed usually refer to short-time results in small, optimized laboratory reactors.

However, acrolein yields depend not only on the chemical compositions of these catalysts, but also on their physical properties, such as shape, porosity, pore-size distribution, and specific surface area, as well as on the reaction conditions and construction of the reactor.

At present the maximum acrolein yield at high propene conversions (up to 98 %) using commercial catalysts is approximately 83 to 90 % with acrylic acid yields of 5 – 10 %. In commercial plants the catalysts are employed at reaction temperatures of 300 – 400 °C, contact times of 1.5 – 3.5 s, and propene concentrations of 5 – 10 vol % of the feed gas at inlet pressures of 150 – 250 kPa. The catalysts have lifetimes of up to ten years, after which they generally have to be replaced. The main reasons for a catalyst change are a reduced economy of the process that is mostly caused by a too low product yield or an increased pressure drop in the reactor.

Production Processes. Production processes are described in [80, 100 – 102]. A simplified flow sheet for the production of acrolein by propene oxidation is shown in Figure 1.

Propene is mixed with air and steam in a molar ratio of approximately 1 : 8 : (1 – 6); steam can be replaced by inert gas, e.g., the off-gas from the absorber. The inlet gas mixture is fed to a multitubular fixed-bed reactor (a) which is cooled by a recirculating molten salt bath.

The reactor is usually operated at 300 – 400 °C with a conversion rate of propene of up to 98 % and inlet pressures of 150 – 250 kPa. The reactor effluent is quenched at the exit to prevent subsequent reactions of acrolein [103]. The reaction gas is then scrubbed with water or water/solvent mixtures in a first column (b) to remove acrylic acid, polymeric compounds, and traces of acetic acid [104]. Byproduct acrylic acid can be recovered from the bottoms [101] and purified; acrylic acid usually forms in 5 to 10 mol % yield based on propene.

The gas is then passed to an absorber (c) where an aqueous solution of acrolein is obtained by absorbing the gas in cold water. Part of the off-gas from the absorber can be used as inert gas for the reactor because it contains only noncondensable components, such as unreacted propene, carbon oxides, oxygen, and nitrogen. The rest is purged as waste gas after it passes through a combustion system.

The aqueous solution of acrolein is sent to a desorption column (d), where it is stripped to give crude acrolein; the bottom stream from this column is cooled and reused as an absorbent. The crude acrolein is distilled to remove low-boiling byproducts, such as acetaldehyde, and heavy ends; acrolein is then obtained as a 96 % pure product that contains only traces of acetaldehyde. Sometimes crude acrolein is used directly. To minimize polymerization, the whole system is stabilized by, e.g., hydroquinone.

New Developments. Selectivity and yield are in the main focus in heterogeneous oxidation catalysis, because the cost of feed materials on the basis of oil escalates. New catalyst materials improve energy and raw materials efficiency and reduce CO_2 formation and emission. Novel approaches to achieve this goal are using oxide nanocatalyst preparation to tune the nature of the active center, oxidant selection to avoid overoxidation, and catalyst arrangement to take advantage of the reaction mechanistic features [105, 106]. An alternative route to acrolein is indicated by numerous publications dealing with the conversion of propane over Mo-V-Te-X-O catalysts [107 – 110]. Actually, new catalysts on the basis of Mo-P-Te-O/SiO_2 and Mo-V-Te/SiO_2 (and MCM 41) show the selective formation of acrolein from propane [111]. However, thermodynamic considerations revealed the limitation of propane as feedstock for the one step synthesis of acrolein [112]. The

Table 2. Industrial catalysts for the selective oxidation of propene to acrolein

two stage process based on a first dehydrogenation step of propane to propene followed by a conventional unit for the oxidation of propene to acrolein (PDH-process). The first stage, the dehydrogenation of propane to propene is already commercial available: UOP (Oleflex-Process), ABB Lummus Global (Catofin-Process), Linde (Linde-Process), Snamprogetti/Yarsintez (Fluidized Bed Dehydrogenation-3-Process). In these technical processes, conversions of 30 to 60 % and selectivity to propene of 90 % are obtained. Important side reactions are cracking and hydrogenolysis of propane and propene. Coke deposits on the catalysts necessitate the regeneration of the catalyst. The total amount of propene that is produced by PDH is about 2 % of the total global amount. The oxidative dehydrogenation of propane (ODH process) is still in the development and has not yet led to a commercial process [113 – 116]. However, the direct combination of propane dehydrogenation and selective oxidation of propene to acrolein has not yet been commercialized.

The MTP process (Methanol to Propene) that was developed by Lurgi uses methanol as feedstock for propene. The zeolite-based catalyst for the fixed bed process was developed by Südchemie AG. This technology increases the basis of the raw materials and is the latest example for the increasing relevance of methanol as basis for the chemical production of the future. It is planned to use methanol from a MegaMethanol plant that is sent to an adiabatic DME prereactor where, methanol is converted to DME and water. A methanol, water, DME stream is routed to the MTP® reactor. DME and methanol is

converted by more than 99% with propylene as main product.

3.2. Methacrolein

Methacrolein (MA) was produced by Union Carbide in the 1950s and early 1960s by 2-methylpropene (isobutene) oxidation over a copper(I) oxide catalyst. Today, several companies produce methacrolein commercially as an organic intermediate that is used as building block for chain expansions. Large quantities of methacrolein are produced by several producers [e.g., BASF, Mitsubishi Rayon, Kyodo Monomer (Kuraray, Mitsui), Nihon Methacrylic Monomer (Nippon Shokubai, Sumitomo), Asahi Kasei] as an intermediate in newly developed processes for the production of methyl methacrylate or methacrylic acid. These processes use either C_4 feedstocks [2-methylpropene (isobutene, IB), *tert*-butyl alcohol (TBA)] or the C_2 hydrocarbon ethylene (via hydroformylation) as raw material. However, around 75 % of methyl methacrylate (MMA) worldwide is still produced by the esterification of methacrylamide obtained from acetone cyanohydrin.

Vapor-Phase Oxidation of 2-Methylpropene or *tert*-Butyl Alcohol. Catalysts for the oxidation of 2-methylpropene or *tert*-butyl alcohol are multicomponent metal oxide systems similar to those used to make acrolein. Most of the catalysts for the oxidation of propene have been claimed in the literature to be suitable for the oxidation of 2-methylpropene or *tert*-butyl alcohol. Typical reaction pressure ranges from above 1 bar to about 5 bar, and reaction temperatures range from 350 to 375°C. Higher temperature permits faster reactions but lower selectivity. The reaction times are typically 2 to 4 sec. However, the yields were generally lower than for acrolein. Yields of 80 – 87 % methacrolein and 1 – 5 % methacrylic acid for 90 – 98 % conversions in short-time laboratory experiments have been reported [117]. At high conversion, product gas must not be recycled. For high selectivity, the process generally requires greater dilution of the feed gas with steam (ca. 8 – 10 vol %) or inert gas (ca. 78 – 80 vol %) than is needed for propene oxidation. Impurities, such as butadiene, often oligomerize on the oxidation catalyst causing serious deterioration of its activity. Methacrolein can be separated and purified before it is fed to a second reactor or can be directly led into the second stage to convert the methacrolein to methacrylic acid (MAA). MAA is finally converted in the liquid phase with methanol to obtain methyl methacrylate.

Several plants for producing methyl methacrylate via methacrolein have been constructed in Japan and Korea. In 1983, Nippon Shokubai brought on stream a 15 000 t/a demonstration plant based on the oxidation of 2-methylpropene [118], and later in the same year Mitsubishi Rayon started a 40 000 t/a commercial plant based on the oxidation of *tert*-butyl alcohol [119]. These were the first plants using the new technology. Process conditions are similar to those for propene oxidation [120, 121].

In 2002, Asahi Kasei added 30 000 t/a of methyl methacrylate (MMA) capacity at its 70 000-t/a plant at Kawasaki, Japan. The company uses proprietary technology for the direct oxidative esterification of methacrolein to MMA [122]. In 2002, nearly half of the Japanese methyl methacrylate capacity of 600 000 t/a (Germany 320 000 t/a, total western Europe 743 000 t/a) [123] was produced with processes based on 2-methylpropene or *tert*-butyl alcohol. This corresponds to an estimated methacrolein capacity of 265 000 t/a.

Production from C_2 and C_1 Feedstocks. ASF has developed a process for the production of methacrolein from C_2 and C_1 feedstocks. Ethylene is hydroformylated to propanal, which can be condensed with formaldehyde in a Mannich type reaction to give methacrolein: For each unit of propionaldehyde produced, approximately 0.5 units of ethylene are required, which reflects a 96 to 97 % yield.

$$CH_2 = CH_2 + CO + H_2 \rightarrow CH_3CH_2CHO$$

$$CH_3CH_2CHO + CH_2O \rightarrow CH_2{=}C(CH_3)CHO + H_2O$$

The Mannich condensation can be carried out in aqueous solution of dimethylamine in the presence of acetic acid to from the Mannich base salt. Methacrolein can be distilled from the resulting solution in a yield of 95 %; the aqueous solution can be recycled [124]. Since 1989

BASF has used this process as one reaction step in their production process for methyl methacrylate starting from ethylene (capacity 36 000 t/a).

Alternatively, the crossed aldol condensation of propionaldehyde and formaldehyde (as trioxane) takes place over molecular sieves such as HAMS-1B/ Al_2O_3 at 300°C. The conversion is around 58 % with 98 % selectivity to methacrolein. No amine is required [125].

Dehydrogenation of Isobutyraldehyde. Methacrolein can be prepared by vapor-phase oxidative dehydrogenation of isobutyraldehyde using a catalyst with heteropoly anions containing molybdenum and phosphorus as the main components [126]. Yields are approximately 80 % methacrolein and 7 % methacrylic acid. However, as long as isobutyraldehyde is available only from propene as a byproduct of the oxo synthesis, this route will not be a major process for methacrolein.

A new method of conversion of isobutane to methacrylic acid, which involves contacting the catalyst with isobutane in gas-phase flow reactor in presence of oxygen under reaction conditions was recently reported [127]. However, the synthesis of methacrolein from isobutane is still a challenge.

4. Quality and Analysis

Quality. Typical specifications (wt %) guaranteed by producers of acrolein are as follows:

Purity of acrolein 95 – 97
Water content < ca. 3
Hydroquinone < 0.1 or 0.2
Acetaldehyde < 0.3

Some producers specify the acetaldehyde limit as < 2 % and indicate propene oxide contents of up to 1.5 %.

Analysis. Impurities include water, acetaldehyde, and, depending on the process, small amounts of propionaldehyde, acetone, propene oxide, methanol, and traces of allyl alcohol and ethanol. The contents of acrolein, water, and acetaldehyde can be determined by gas chromatography with a thermal conductivity detector. The Karl Fischer method is not applicable for determining the water in acrolein. Hydroquinone is determined colorimetrically using Millon's reagent to form a yellow complex [10].

5. Handling, Storage, and Transportation

Acrolein is classified as a very toxic, flammable liquid. The liquid vaporizes easily and the vapors are readily flammable in air at between 2.8 and 31.0 vol%. Acrolein vapors are twice as heavy as air. The flash point, − 26 °C, is very low. Preferred fire-fighting agents are foam, powder (not alkaline), spray water, and carbon dioxide. The high toxicity and volatility of acrolein necessitate the use of a respirator in case of fire.

Acrolein polymerizes easily and exothermally; therefore it is stabilized with 0.1 or 0.2 % hydroquinone against radical-initiated polymerization, which can be catalyzed by light, air, heat, or peroxides. Acrolein should be stored and transported in the dark under a blanket of nitrogen at temperatures below 20 °C, and it should be used within three months. The hydroquinone content should be determined (see Chap. 4) and if it is below 0.05 %, hydroquinone must be added to bring it up to 0.1 %.

Highly exothermic ionic polymerization is catalyzed by alkaline compounds, such as caustic soda, ammonia, and amines, or by mineral acids, such as concentrated sulfuric acid. These chemicals initiate polymerization at an explosive rate. Because even a trace amount of contaminant can initiate polymerization, equipment for acrolein handling must be cleaned thoroughly before use. Common inhibitors such as hydroquinone are *absolutely not effective* in preventing these ionic polymerization reactions. Depending upon the amount of ionic contaminants, the temperature rise may be slow enough that the injection of an emergency buffer solution (84 % acetic acid, 8 % hydroquinone, 8 % anhydrous sodium acetate) suffices to control further reaction. Addition of water to stored acrolein must be avoided completely. The acrolein-containing water layer is particularly prone to polymerization. Acrolein vapors polymerize upon condensation.

Because acrolein is toxic, it is not allowed in wastewaters. It is also strongly lacrimatory,

and contact with skin and eyes must be strictly avoided because exposure can result in severe injury. But it can be handled safely under controlled conditions in properly designed equipment [128].

Regulations Governing Transport. Acrolein is classified as a dangerous, flammable, and poisonous substance in various international and regional regulations. For the transportation of inhibited acrolein, the following regulations are mandatory:

International sea transport (IMDG Code): Class 6.1, UN no. 1092, PG I. International air transport (IATA-DGR): forbidden. European road (ADR) and rail (RID) transport: Classes 6.1, 8a). Proper shipping name: Acrolein, inhibited. National regulations: United States (CFR 49): § 172.101 Toxic liquid, flammable. Germany (GGVS): Special permission required for road transport of 1000 kg or more if transported in tanks with a capacity exceeding 3000 L.

For the transportation of inhibited methacrolein the following regulations are mandatory:

International sea transport (IMDG Code): Class 3.2, UN-No. 2396, PG. II. International air transport (IATA-DGR): Class 3, UN no. 2396, PG II. European road (ADR) and rail (RID) transport: Class 3, 17b). Proper shipping name: Methacrylaldehyde, inhibited. National regulations: United States (CFR 49): § 172.101 Flammable liquid, toxic.

6. Uses and Production Data

Methacrolein is an intermediate in two processes for the production of methyl methacrylate: the oxidation of 2-methylpropene or *tert*-butyl alcohol (see Section 3.2) and the Mannich reaction of propionaldehyde with formaldehyde (see Section 3.2). It has also found limited commercial application in the synthesis of flavors and fragrances [129].

Acrolein is a useful chemical intermediate used for the production of numerous chemical products. It is used commercially as a very effective broad-spectrum biocide in very low concentrations of approximately 10 ppm [130, 131]. For example, it is applied to control the growth of aquatic weeds in irrigation waterways [132] or of algae and mollusks in recirculating water systems [131, 133]. Of particular importance is the use of acrolein as a biocide in oil-field brines; it increases the efficiency of oil-field water flooding and is useful in brine disposal operations. Furthermore, it is used in oil-field waters to scavenge malodorous hydrogen sulfide completely [134].

The main field of use includes the production of methionine, methionine hydroxy analog, acrylic acid, 1,3 propanediol, glutaraldehyde, pyridines, flavors and fragrances.

Methionine. Acrolein is mostly used for the production of methionine [*59-51-8*] (→ Amino Acids), which is used as an animal feed supplement [2]. Acrolein is also used to make the methionine hydroxy analogue ($CH_3SCH_2CH_2CH(OH)COOH$) [*583-91-5*], either as an 88 % aqueous solution [135, 136] or the calcium salt [137]. Different values for the bioefficacy of this acid have been published, but it is about 22 – 28 % lower than that of D,L-methionine on an equimolar basis.

Acrylic acid is another commercially important product derived from acrolein (→ Acrylic Acid and Derivatives). It is used to make acrylates.

1,3-Propanediol (→ Propanediols) can be produced by the Degussa/DuPont process from acrolein. Acrolein is hydrolyzed with a acid catalyst to 3-hydroxypropionaldehyde that is hydrogenated to 1,3-propanediol. The process was in operation in Cologne-Wesseling/Germany. Recently, DuPont announced to start the production of bio-propanediol in 2007 by fermentation. Propanediol can be formulated, e.g., into composites, laminates, powder, adhesives and UV-cured coatings, novel aliphatic polyesters, copolyesters, solvents, moldings and anti-freeze [138, 139].

Glutaraldehyde, glutardialdehyde (for preparation from acrolein, see page 2), is supplied industrially in the form of a 25 % or a 50 % aqueous solution; the anhydrous compound is unstable. This dialdehyde is used mainly for leather tanning [140]. Applications also include use as a biocide for industrial water treatment and in oil-field applications [141] and as a dis-

infectant and chemical sterilizer for hospital equipment [142].

Pyridines. Only Daicel is currently using acrolein in the commercial synthesis of 3-methylpyridine (see page 4). Other substituted pyridines can be prepared from acrolein and substituted acroleins [52, 143, 144] (→ Pyridine and Pyridine Derivatives).

Tetrahydrobenzaldehyde (see page 2) is another interesting product, e.g., for the synthesis of pharmaceuticals, fungicides [145], and fragrances [146].

Flavors and Fragrances. A broad variety of compounds, synthesized mainly by Diels – Alder reactions of acrolein or methacrolein (see page 2), are described as flavors and fragrances. Commercially interesting substances are, for example, lyral (**5**) [*31906-04-4*] [147, 148], myrac aldehyde (**6**) [*80450-04-0*] [148], and 5-norbornene-2-carbaldehyde (**7**) [149].

5

6 **7**

Herbicides. Acrolein cyanohydrin acetate is produced as an intermediate for the production of phosphinotrycin, a nonselective herbicide. Phosphinotrycin is very effective in crop protection together with genetically modified phosphinotrycin-resistant crops [150].

Allyl Alcohol and Glycerol. In a process developed by Shell in 1959, allyl alcohol was synthesized from acrolein by hydrogen transfer from 2-propanol in the vapor phase. The allyl alcohol was then reacted with hydrogen peroxide to form glycerol. However, this process was closed down in 1980.

D,L-Glyceraldehyde (see page 5), which is commercially available as a 40 % aqueous solution, has been proposed as a water-soluble hardener for leather tanning and related applications, as well as for various syntheses.

Acrolein Polymers. Acrolein itself has seldom been used as a monomer for commercial polymerization because of the difficulty in orienting its mode of polymerization and the likelihood of complex cross-linking leading to insoluble products. However, a poly(aldehyde carboxylic acid), produced by oxidative copolymerization of acrolein and acrylic acid [151], is applied industrially as a sequestering agent [152]. Furthermore, many applications of acrolein polymers have been proposed, including those in textile treatment [153], reinforcement of paper [154], and photography [155]. The water-soluble polymeric condensation product of acrolein and formaldehyde in 40 % aqueous solution is used as a biocide, e.g., as an algicide in recirculating cooling waters [156].

Production Data. The production capacities (t/a) of acrolein in the western Europe, USA, and Japan are estimated as follows:

Degussa	150 000
DOW	80 000
Adisseo	80 000
Arkema	70 000
Sumitomo Chem.	35 000
Daicel	10 000

Moreover, all acrylic acid processes involving vapor-phase propene oxidation include the intermediate production and consumption of acrolein.

7. Toxicology and Ecotoxicology

7.1. Toxicology

Acrolein is severely irritating to the skin and the mucous membranes. Its vapor causes strong eye and nasal irritation. Direct contact of liquid acrolein with the eye or skin results in severe burns. Acrolein is very toxic after inhalation exposure and toxic after oral administration and skin contact [157].

Acute toxicity data are:

LD_{50} (rat, oral)	< 11 up to 46 mg/kg
LD_{50} (rabbit, skin, neat acrolein)	562 mg/kg
LD_{50} (rabbit, skin, 20 % aqueous acrolein solution)	335 mg/kg
LC_{50} (rat, inhalation, 4 h)	0.02 mg/L

Even very dilute solutions of acrolein are strongly irritating to skin and mucous membranes [158]. Severe damage to the eye was observed in rabbits with a 1 % acrolein solution in glycol [159]. Due to the high reactivity of the acrolein molecule it is primarily bound locally to the application site. After absorption in the gastrointestinal tract, the main pathway of biotransformation is conjugation with glutathione and subsequent oxidation or reduction of the aldehyde group [158]. Acrolein was reported to be nonsensitizing in the guinea pig maximization test [158].

In subacute to chronic inhalation studies conducted in various species, irritation and inflammation with hyper- and metaplastic changes in the respiratory tract were the primary observed effects. At higher exposure concentrations, additional inflammatory changes in the liver and kidney were observed. After exposure for 13 weeks, (6 h/d, 5 d per week), a concentration of 0.9 mg/m^3 was proven to be the No-Observed-Adverse-Effect Level (NOAEL) in hamsters and rabbits [160], while exposure for 8 to 13 weeks (6 h/d, 5 d per week) at a concentration of 0.9 mg/m^3 caused slight damage to the nasal mucosa and the lung epithelium in some strains of rat [160 – 162]. After continuous exposure of rats (24 h/d, 7 d per week) for 61 d, the NOAEL was 0.15 mg/m^3 [158].

Chronic oral administration of acrolein to rats, mice and dogs resulted in reduced body weight gain, increased mortality and changes in clinicochemical parameters at high dosages. Pathological organ changes, however, were not observed. The NOAEL for rats and dogs was 0.5 mg/kg and 2.0 mg/kg for mice [158].

In vitro acrolein reacts with nucleic acids and inhibits their synthesis. On the basis of the high cytotoxicity as well as the high reactivity of acrolein, there are difficulties in testing the genotoxic potential. From the available studies it may be concluded that acrolein seems to show genotoxic properties predominantely at high, cytotoxic concentrations in in vitro test systems (bacteria, yeasts, mammalian cell cultures), while no mutagenic properties were noted in in vivo studies in mammalian animals [158, 163].

Acrolein is noncarcinogenic after oral administration to rats and mice. After inhalation exposure of hamsters for 52/81 weeks no increase in tumor incidence was observed. In a dermal initiation/promotion study in mice (18 weeks) there was no indication of a possible cocarcinogenic effect of acrolein [158].

Acrolein is classified by IARC in group 3 (inadequate evidence for carcinogenicity in humans, with inadequate evidence in experimental animals and no information in humans) [164].

Acrolein did not show any reproductive or developmental toxicity after oral or inhalative exposure in multigeneration experiments in rats [158, 163]. No developmental toxicity was observed in doses that were not maternally toxic after oral and i.v. administration in rabbits. The overall NOAEL in teratogenicity studies was 2 mg/kg bw per day or higher for developmental effects and 0.75 mg/kg bw per day for parental effects [158, 163].

In humans exposed to acrolein vapors for 5 min, an increased frequency of eyelid closure was observed at 0.69 mg/m^3 and a decrease in respiratory frequency at 1.4 mg/m^3 [165]. The odor threshold was reported to be between 0.05 and 0.8 mg/m^3. At 0.23 mg/m^3, 50 % of the test persons were able to detect the odor [158]. Thus the odor threshold seems to be close to the threshold for eye irritation.

Occupational exposure limits are 0.1 ppm (0.25 mg/m^3) in Germany (8 h TWA and STEL) [166], and 0.1 ppm (0.23 mg/m^3, 8 h TWA), 0.3 ppm (0.7 mg/m^3, STEL) in the United Kingdom [167], and 0.1 ppm (0.23 mg/m^3) ceiling level the United States [168]

Methacrolein is of moderate toxicity after oral, dermal, and inhalative administration to experimental animals.

Acute toxicity data are:

LD_{50} (rat, oral)	140 mg/kg
LD_{50} (rabbit, skin)	111 mg/kg
LC_{50} (rat, inhalation, 4 h)	560 mg/m^3

The effects after inhalative exposure are characterized by irritation of the respiratory tract [169]. A sensory irritation study in mice revealed a 50 % reduction in the respiration rate (RD_{50}) at exposure concentrations of methacrolein vapors of 10.4 ppm following a 30-min exposure period [170].

Methacrolein is corrosive to rabbit skin and severely irritating to rabbit eyes in concentrations of 1 – 5 %. Therefore undiluted

methacrolein is expected to be corrosive to the eye [169].

After subacute (15 d, 6 h/d, 5 d per week) and subchronic (90 d, 6 h/d, 5 d per week) inhalation in rats, the only adverse effect observed was severe irritation of the upper, middle, and lower respiratory tract. The NOAEL was 13 mg/m^3 (14 d study) and 14 mg/m^3 (90 d study) respectively. In the 90 d study, signs of reversibility were observed within the four week recovery period [169].

In humans exposed to methacrolein vapors for 10 min, the eye blinking rate was increased at a concentration of 0.29 ppm, the NOAEL in this study was 0.19 ppm [170]

Methacrolein showed conflicting results in mutagenicity tests in microorganisms [169], which may be related to bacteriotoxic effects. In an in vitro chromosomal aberration assay in Chinese hamster V79 cells, methacrolein caused structural chromosomal aberrations with and without metabolic activation [169].

No embryotoxic or teratogenic effects were observed in maternally nontoxic doses in an inhalation study for developmental toxicity in rats [169].

7.2. Ecotoxicology

Acrolein is of moderate to high toxicity towards aquatic organisms and microorganisms. Toxicity does not seem to increase considerably with exposure time. Ranges of acute toxicity on species of three trophic levels including microorganisms are as follows: In fish LC_{50} (24 – 96 h) values ranged from 0.014 to 2.5 mg/L. In amphibia (tadpoles) an LC_{50} (96 h) of 0.007 mg/L was reported, Daphnia showed EC_{50} (24 – 48 h) values between 0.022 and 0.093 mg/L. In green algae the EC_{50} (1 – 25 h) was 0.69 – 1.8 mg/L. Microorganisms showed IC_{10} (16 – 48 h) values of 0.04 – 1.7 mg/L [158].

Acrolein in a concentration of 1.4 mg/m^3 damaged the leaves of higher plants after an exposure period of 3 h in a fumigation chamber. No toxic effects occurred after 9 h exposure at a concentration of 0.233 mg/m^3 [158].

In a three-generation chronic toxicity study (64 d) in *Daphnia magna*), the MATC (maximal acceptable toxicant concentration) in the second and third generation for reproductive toxic effects ranged from 0.0169 to 0.0336 mg/L [158].

Biodegradation of acrolein only takes place with adapted microorganisms [158]. Based on the low octanol/water partition coefficient (log P_{ow} = − 1.1 – 1.02 [3]) and its high reactivity, bioaccumulation of acrolein is not expected.

Methacrolein. Data on environmental distribution of methacrolein indicate that the majority of the substance will distribute from water bodies to air. At 25 °C, only 0.02 % of the total methacrolein present will remain in the water phase [171]. No data on fish, daphnia, or algae toxicity are available. In a respiration inhibition test with activated sludge, the toxicity threshold concentration of methacrolein was 0.05 mmol/L. Biodegradation, measured as BOD, was about 35 % after 10 d with unadapted microorganisms and > 60 % after 8 d with adapted microorganisms. This indicates ready biodegradability only after acclimatization [172]. Due to its low octanol/water partition coefficient (log P_{ow} = 0.59 [173]) bioaccumulation of methacrolein is not expected.

Abstract

The article contains sections titled:

1. Acrylic Acid and Esters
1.1. Physical Properties
1.2. Chemical Properties
1.3. Production
1.3.1. Propene Oxidation
1.3.2. Esterification
1.4. Quality Specifications and Analysis
1.5. Storage and Transportation
1.6. Uses
1.7. Some Special Acrylates
1.8. Economic Aspects
1.9. Toxicology and Occupational Health
2. Cyanoacrylates
3. Acrylamide

[Top of Page]

1. Acrylic Acid and Esters

Acrylic acid [79-10-7], 2-propenoic acid, CH_2=CHCOOH, and its esters CH_2=CHCOOR, which are also known as acrylates, are flammable, volatile, mildly toxic, colorless liquids. Hydroquinone or its monomethyl ether is usually added to commercial preparations to inhibit polymerization. Formerly, acrylic acid and acrylates were produced industrially via a variety of routes such as acrylonitrile hydrolysis and the modified Reppe process (see Section Production). However, remarkable progress on the catalytic oxidation of propene to acrylic acid via acrolein has led to almost complete replacement of these earlier processes.

Esters such as methyl, ethyl, *n*-butyl, and 2-ethylhexyl acrylates, as well as acrylic acid, are in worldwide use, primarily for polymers. Other esters, including multifunctional acrylates, are produced for special applications.

Chemically, *acrylamide* (see Chap. Acrylamide) is a derivative of acrylic acid but the amide is produced by hydration of acrylonitrile instead of by amidation of the acid.

1.1. Physical Properties

Acrylic Acid is a clear, colorless liquid, *bp* 141.0 °C (101.3 kPa), *mp* 13.5 °C; it forms crystalline needles in the solid state. Other important physical constants are listed below [1-6]:

M_r	72.06
Refractive index	n_D^{20} 1.4224, n_D^{25} 1.4185
Density	1.060 (10 °C), 1.040 (30 °C), 1.018 (50 °C) g/cm^3
Viscosity at 25 °C	1.149 mPa · s
Critical temperature	380 °C
Critical pressure	5.06 MPa
Heat of vaporization at 101.3 kPa	45.6 kJ/mol
Heat of combustion	1376 kJ/mol
Heat of melting at 13 °C	11.1 kJ/mol
Heat of neutralization	58.2 kJ/mol
Heat of polymerization	77.5 kJ/mol
Dissociation constant at 25 °C	5.5×10^{-5}; $pK_a = 4.26$

Vapor pressure as function of temperature:

1.2. Chemical Properties

Acrylic acid and its esters undergo reactions characteristic of both unsaturated compounds and aliphatic carboxylic acids or esters. The high reactivity of these compounds stems from the two unsaturated centers situated in a conjugated position. The β carbon atom, polarized by the carbonyl group, behaves as an electrophile; this favors the addition of a large variety of nucleophiles and active hydrogen compounds to the vinyl group. Moreover, the carbon-carbon double bond undergoes radical-initiated addition reactions, Diels–Alder reactions with dienes, and polymerization reactions.

The carboxyl function is subject to the displacement reactions typical of aliphatic acids and esters, such as esterification and transesterification.

Joint reactions of the vinyl and carboxyl functions, especially with bifunctional reagents, often constitute convenient routes to polycyclic and heterocyclic substances.

Acrylic acid and its esters polymerize very easily. The polymerization is catalyzed by heat, light, and peroxides and inhibited by stabilizers, such as the monomethyl ether of hydroquinone or hydroquinone itself. These phenolic inhibitors are effective only in the presence of oxygen. The highly exothermic, spontaneous polymerization of acrylic acid is extremely violent.

In this section are listed typical examples of reactions other than polymerization, which is discussed in Section Uses. Several review articles and monographs [1-7] describe the rich chemistry of acrylates and acrylic acid.

Addition Reactions. Acrylic acid and acrylates combine readily with substances, such as hydrogen, hydrogen halides and hydrogen cyanide, that customarily add to olefins [8]:

$$H_2C = CHCOOR + HX \rightarrow H_2CX - CH_2COOR$$

where R = H, alkyl, or aryl, and X = H, halogen, or CN.

Michael additions of organic substances take place in the presence of basic catalysts, such as tertiary amines, quaternary ammonium salts, and alkali alkoxides:

$$\text{where } X = -C(NO_2)R'R'',\ -CH(COOR')_2,\ -CH\begin{matrix}COOR'\\COR''\end{matrix},\ -CH\begin{matrix}CN\\COOR'\end{matrix},\ \text{or } -CH\begin{matrix}CN\\C_6H_5\end{matrix}$$

and R′, R″ = alkyl or aryl.

Ammonia and amines are sufficiently basic to react without a catalyst: where X = $–NH_2$, –NHR′ [9], [10], –NR′R″ [11], heterocycles [12-14], –NR′COR″, or $–NHNR_2$ [15]. The addition of only one molecule of NH_3 (for addition of two, see below) can be achieved with an aqueous solution of ammonia and ammonium carbonate [16].

The addition of aromatic amines or amides and *tert*-alkyl primary amines is more effectively promoted by acids. Amines may attack both the vinyl and carboxyl functions, but the products of such reactions decompose to give N-substituted amides.

Alcohols [17], phenols, hydrogen sulfide [14], [18], and thiols [19], [20] also add under basic conditions. Hydrogen sulfide in the presence of sulfur and ammonium polysulfide or amine catalysts gives polythiodipropionic acids and esters [19], [21]:

$$CH_2{=}CH{-}COOR \xrightarrow[S,\,H_2S]{(NH_4)_2S_x} S_x(CH_2CH_2COOR)_2$$

where R = H, alkyl, or aryl.

Other examples of HX additions to acrylic acid and acrylates are:

$$\text{where } X = -O_2SR',\ -SO_3Na,\ -OP(OR')_2,\ -\overset{O}{\overset{\|}{C}}{-}R'\ [22],[23],$$

, or

(24)

and R′ = alkyl or aryl [22-24].

Additions of aromatic hydrocarbons are promoted more efficiently by Lewis acids [25].

If further acidic hydrogen atoms are available in the addition product, a second (and third) molecule of acrylic acid or ester adds. This is the case in the reaction of acrylic acid or ester with H_2S, NH_3, RNH_2, and pyrrole.

Other examples of addition reactions are the following:

$$H_2C{=}CH{-}COOR + Hal_2 \longrightarrow \underset{Hal}{CH_2}{-}\underset{Hal}{CH}{-}COOR\ [26]$$

$$+ HOCl \longrightarrow \underset{OH}{CH_2}{-}\underset{Cl}{CH}{-}COOR\ [3]$$

$$+ Hg(OCOCH_3)_2 + CH_3OH \longrightarrow \underset{OCH_3}{CH_2}{-}\underset{HgOCOCH_3}{CH}{-}COOR + CH_3COOH\ [3]$$

$$+ C_6H_5N_2^+Cl^- \longrightarrow \underset{C_6H_5}{CH_2}{-}\underset{Cl}{CH}{-}COOR + N_2\ [3]$$

$$+ CH_2{=}C(CH_3)_2 \longrightarrow CH_2{=}\underset{CH_3}{C}{-}CH_2CH_2CH_2COOR\ [3],\ [27]$$

where R = H, alkyl, or aryl [3, 26, 27].

Heterocyclic substances often can be formed by subsequent reaction of the carboxyl function, especially with bifunctional nucleophiles [23], [28]:

where R = H, alkyl, or aryl.

Substituted ring compounds are formed readily by Diels–Alder reactions [30], [31]:

Acrylates also undergo cobalt- or rhodium-catalyzed hydroformylation reactions [32], [33]:

$$2\,CH_2{=}CH{-}COOR + 2\,CO + 2\,H_2 \xrightarrow{\text{catalyst}} CH_2(CHO){-}CH_2COOR + CH_3CH(CHO){-}COOR$$

where R = alkyl or aryl.

At elevated temperature or on longer storage acrylic acid dimerizes:

$$2\ CH_2 = CH - COOH \rightarrow CH_2 = CH - COOCH_2CH_2COOH$$

In the presence of catalysts such as tributylphosphine, acrylates can also dimerize to give 2-methyleneglutarates [34]:

$$2\,CH_2{=}CH{-}COOR \xrightarrow{\text{catal.}} ROOC{-}\overset{\overset{\displaystyle CH_2}{\|}}{C}{-}CH_2CH_2{-}COOR$$

where R = alkyl or aryl.

Reactions of the Carboxyl Group. Acrylic acid is converted readily into its corresponding salts, into acrylic anhydride by reaction with acetic anhydride, or into acryloyl chloride by reaction with benzoyl or thionyl chloride. The esterification of acrylic acid and transesterification of acrylic esters are economically the most important reactions (see Section Esterification).

Some other examples are:

where R′, R″ = alkyl or aryl [35-37].

1.3. Production

Commercial acrylic acid is mostly produced from propene, which is also the raw material for the production of acrolein. In the past, acrylic acid and its esters were produced by various processes some of which are summarized here (see [5], [6], [38], [39]) and are still in use to a small extent.

Processes Based on Acetylene (⟶ Acetylene). The stoichiometric synthesis of acrylic acid and its esters from acetylene proceeds at atmospheric pressure and at 40 °C in the presence of acid and nickel carbonyl:

$$4\ C_2H_2 + 4\ ROH + 2\ HCl + Ni(CO)_4 \rightarrow 4\ CH_2 = CHCOOR + NiCl_2 + H_2$$

where R = H, alkyl, or aryl.

The reaction was discovered by W. REPPE in 1939. Röhm & Haas and Toa Gosei Chemical have used this method as well as the modified, non-stoichiometric Reppe process, but both have been abandoned because of the difficulties in handling the toxic and corrosive nickel carbonyl.

High-Pressure Reppe Process. The process employed by BASF and Badische Corp. proceeds at approximately 14 MPa and 200 °C with a nickel bromide – copper(II) bromide catalyst:

$$C_2H_2 + CO + H_2O \xrightarrow{\text{catal.}} CH_2{=}CHCOOH$$

However, the safety and pollution control problems with nickel carbonyl (formed in the process) and the high cost of acetylene are disadvantages of this process. It has largely been replaced by the direct oxidation of propene although BASF still produces part of its acrylic acid by this process.

Acrylonitrile Hydrolysis (⟶ Acrylonitrile). This method is economically unattractive because of the low yield based on propene and the large quantities of NH_4HSO_4 waste. The process has been abandoned by Ugine Kuhlmann, Mitsubishi Petrochemical, and Mitsubishi Rayon. However, it is still on stream at Asahi Chemical.

Ketene Process [6], [40]. Acetic acid or acetone is pyrolyzed to ketene in this process which has long been abandoned by Celanese and B. F. Goodrich. The many steps and toxicity of β-propiolactone are major disadvantages.

R = H or alkyl.

Ethylene Cyanohydrin Process. Ethylene cyanohydrin is generated by addition of hydrogen cyanide to ethylene oxide. The product then is hydrolyzed to acrylic acid using sulfuric acid. This process was used by Union Carbide and Röhm & Haas, but has been abandoned because of problems in dealing with HCN and the NH_4HSO_4 waste.

1.3.1. *Propene Oxidation*

Propene oxidation involves heterogeneous catalytic oxidation of propene in the vapor phase with air and steam to give acrylic acid. Generally the product leaving the reactor is absorbed in water, extracted with an appropriate solvent, and then distilled to give technical grade glacial acrylic acid.

Oxidation Catalysts. Research on catalysts for propene oxidation to acrylic acid began in the latter half of the 1950 s. The two methods for the heterogeneously catalyzed gas-phase oxidation of propene are single-step and two-step processes:

Single-step process:

$$CH_2{=}CHCH_3 + 3/2\ O_2 \rightarrow CH_2{=}CHCOOH + H_2O \quad \Delta H = -594.9\ \text{kJ/mol}$$

Two-step process:

$$CH_2{=}CHCH_3 + O_2 \rightarrow CH{=}CH_2CHO + H_2O \quad \Delta H = -340.8\ \text{kJ/mol}$$

$$CH_2{=}CHCHO + 1/2\ O_2 \rightarrow CH_2{=}CHCOOH \quad \Delta H = -254.1\ \text{kJ/mol}$$

Many patents have been issued in both cases. The yield in the *single-step process* is at best approximately 50 – 60 % [38], [41-43]. Another drawback is limited lifetime of the catalyst, which is a multicomponent system composed of polyvalent oxides with molybdenum oxide as the main component and tellurium oxide as the promoter. The life of the catalyst is short because of the tendency of tellurium oxide to sublime.

The *two-step reaction* (Fig. 2) requires different reaction conditions and different catalysts to produce optimum conversion and selectivity in each step. Research has focused on this process, in which the oxidation of propene to acrolein and the oxidation of acrolein to acrylic acid employ separate catalysts. The steps are operated at different temperatures to permit high overall efficiency.

Figure 2. Schematic diagram of acrylic acid production (oxidation section)

First-stage catalysts are acrolein-selective propene-oxidation catalysts. The total yield of acrolein and acrylic acid is more than 85 % (⟶ Acrolein and Methacrolein).

The early second-stage catalysts [43] for acrolein oxidation to acrylic acid were based mainly on cobalt-molybdenum oxides [44]. They had fairly low activity even at high reaction temperatures and gave yields of less than 70 mol %. Most catalysts are composed of molybdenum and vanadium oxides. In 1959, Distillers first proposed a molybdenum-vanadium catalyst system in which the atomic ratio of molybdenum to vanadium was one-to-one [45]. The maximum yield obtained was 30 % at about 400 °C. Since then further studies have shown that only a relatively small amount of vanadium is required. In addition, other elements and carriers have been shown to increase the activity and yield. They have been used for the preparation of multi-component metal-oxide catalysts that contain one or more of the elements copper, arsenic, uranium, aluminum, tungsten, silver, manganese, germanium, gold, barium, calcium, strontium, boron, tin, cobalt, iron, or nickel in addition to molybdenum and vanadium. Supported on an aluminum sponge, the catalyst described in [46] shows good activity and yield. Table 5 lists patented acrolein oxidation catalysts that have relatively high activities and yields. All of these catalysts are metal oxides.

Table 5. Catalyst for the second step of acrylic acid production

Catalyst composition (support) neglecting oxygen	Reaction temperature, °C	Acrolein conversion, %	One-pass yield of acrylic acid, mol %	References
$Mo_{12}V_{1.9}Al_{1.0}Cu_{2.2}$ (Al sponge)	300	100	97.5	[46]
$Mo_{12}V_3W_{1.2}$ (SiO_2)	240	98.0	87.0	[47]

$Mo_{12}V_2W_2Fe_3$	230	99.0	91.0	[49]
$Mo_{12}V_3W_{1.2}Cu_1Sb_6$	272	99.0	91.0	[50]
$Mo_{12}V_{4.6}Cu_{2.2}W_{2.4}Cr_{0.6}$ (Al_2O_3)	220	100.0	98.0	[51]
$Mo_{12}V_2(Li_2SO_4)_2$	300	99.8	92.4	[52]
$Mo_{12}V_{4.8}Cu_{2.2}W_{2.4}Sr_{0.5}$ (Al_2O_3)	255	100.0	97.5	[53]
$Mo_{12}V_{2.4}Cu_{0.24}$ (SiC)	290	99.5	94.8	[54]
$Mo_{12}V_3W_{1.2}Ce_3$	288	100	96.1	[55]
$Mo_{12}V_{4.7}W_{1.1}Cu_{6.3}$	260	99.0	96.0	[56]

Process Conditions. The conditions in the first step correspond to conditions in the acrolein synthesis (see ⟶ Acrolein and Methacrolein – Production). The catalysts used in the second step require reaction temperatures from 200 to 300 °C and contact times from 1 to 3 s. They give almost 100 % conversion of acrolein and yields of acrylic acid greater than 90 %.

Acid Recovery and Purification. The effluent gas from the second-stage multi-tube reactor in Figure 2 is cooled to about 200 °C and then fed to the absorbing column to be scrubbed with water. Because the effluent gas contains a large amount of steam, acrylic acid usually is obtained as an aqueous solution of 20 to 70 wt % [57]. Alternatively, the acid may be absorbed by an organic solvent such as biphenyl, diphenyl ether, or a carboxylic ester with a boiling point higher than 160 °C [58]. Then the steam in the reaction gas does not condense in the absorbing column, but is discharged with other gases from the column top. This method reduces energy consumption in the subsequent purification step, but it also increases the loss of acrylic acid and solvent from the column top.

After the absorption in water, the acrylic acid is purified by extraction with an organic solvent and then distillation. Various solvents can be used for the extraction. The first group (light solvents) includes those with boiling points lower than acrylic acid, such as ethyl acetate, butyl acetate, ethyl acrylate, and 2-butanone, as well as combinations of these [59]. The second group (heavy solvents) has boiling points higher than acrylic acid (e.g., *tert*-butyl phosphate, isophorone, and aromatic hydrocarbons [60]). Mixtures of these light and heavy solvents form a third group [61], [62].

Figure 3 represents the separation and purification process using a *light extraction solvent*. The aqueous acrylic acid from the absorbing column is introduced into the extraction column (a) countercurrent to an organic solvent. The solvent must have a high distribution coefficient for acrylic acid and low solubility in water, and it must form an azeotrope containing a high

percentage of water. The extract from the top of the extraction column goes to the solvent-separation column (c), where the solvent and water are distilled overhead and the solvent is separated and recycled to the extraction column.

Figure 3. Schematic diagram of acid recovery and purification section

a) Extraction column; b) Raffinate-stripping column; c) Solvent-separation column; d) Light-ends cut column; e) Product column; f) Decomposition evaporator

The bottom stream from the extraction column and the water from the overhead of the solvent-separation column are sent to the raffinate-stripping column (b), where a small amount of solvent is recovered by distillation. The waste water from the raffinate-stripping column is biologically treated or incinerated.

The bottom fraction from the solvent-separation column is fed to the light-ends cut column (d), where acetic acid is distilled off and, if desired, recovered. The crude acrylic acid from the bottom of the light-ends cut column is sent to the product column (e), where acrylic acid of high purity is obtained overhead. The material from the bottom of the product column containing acrylic acid dimer is fed to the evaporator (f), where the dimer is decomposed to the monomer. The evaporator residue, composed of acrylic acid oligomers, polymers, and inhibitors, is withdrawn and burned as waste oil.

Because acrylic acid is readily polymerized, distillation columns are operated with an inhibitor, such as hydroquinone or hydroquinone monomethyl ether, in the presence of oxygen, and at reduced pressure to lower the distillation temperature. The purity of acrylic acid produced by this process usually exceeds 99.5 wt %, and the purified yield is about 98 %.

In a *heavy-solvent extraction process* the solvent is not distilled and therefore the energy consumption is less than in a light-solvent process. However, other problems exist, such as the loss of solvent by decomposition and the inferior quality of the product. In the processes using mixtures of light and heavy solvents, the purification system is complex. The light-solvent process is therefore the most suitable for a commercial plant.

Other purification methods also have been reported. In one of these, the acrylic acid is first oligomerized in aqueous solution in the presence of a catalyst such as sulfuric or phosphoric acid. Next the water is distilled, and finally the residual oligomer is decomposed at 120 to 200 °C to obtain acrylic acid [63]. In another process, the acrylic acid is extracted from the aqueous solution with butyl acrylate or octanol. It is then directly esterified with an alcohol to form an acrylate without isolation of the acrylic acid [64], [65]. These processes have not yet been used commercially, probably because of high energy consumption or problems with the product quality.

1.3.2. *Esterification*

Although acrylic acid can be esterified in the vapor phase [66], [67], the liquid phase esterification is industrially more important. Two types of acid catalyst are used: a strong acid, such as sulfuric acid or *p*-toluenesulfonic acid [68], or a solid acid, such as a cation-exchange resin [69]. Although sulfuric acid is superior to ion-exchange resins, its use causes problems in waste disposal. In general, cation-exchange resins are favored for esterification using such alcohols as methanol and ethanol, whereas sulfuric acid is favored for higher alcohols having slower rates of esterification (e.g., pentanols and octanols). Liquid phase reaction of acrylic acid with ethylene in the presence of sulfuric acid does not seem economically feasible for producing ethyl acrylate [70], because of the large quantities of sulfuric acid that are needed.

Lower Alkyl Acrylates (see Fig. 4). Acrylic acid and a small excess (10 – 30 %) of an alcohol are fed into the fixed-bed reactor (a) which is packed with a cation-exchange resin and operated at a temperature of 60 to 80 °C. The reaction liquid then goes to the ester stripper (b) where the desired ester, water, and unreacted alcohol are removed overhead using part of the bottoms from the light-ends column (e) as reflux. The bottom liquid from b contains unreacted acid and is recycled to the reactor. Part of the recycled liquid is fed into the bottom stripper (c), where high-boiling materials, such as inhibitors, impurities, and polymers, are removed to prevent their accumulation in the reaction system.

The acid-free mixture of ester and alcohol distilled from the ester stripper (b) is fed into the extraction column (d), where the alcohol is extracted with water fed from the top of the column. The raffinate from the top of the column goes into the light-ends cut column (e), where light-ends such as water, acetate, and alcohol are separated overhead.

The extract from the bottom of the extraction column is fed into the alcohol recovery column (f), where the alcohol is recovered for reuse in the reaction. Part of the bottom liquid is reused as extracting water; the rest is taken out as waste, concentrated, and either treated biologically or incinerated.

Crude ester from the bottom of the light-ends column is distilled in the product column (g) to obtain acrylate of high purity. The bottom liquid from the product column is recycled (via the inhibitor tank) to the ester stripper (b) and light-ends cut column (e) to be reused as an inhibitor. However, a part of it is sent to the bottom stripper (c) to recover ester and separate high-boiling materials such as polymers.

Polymerization inhibitors, such as hydroquinone or phenothiazine, are added to each column. The light-ends cut column and the product column are operated at reduced pressure to permit lower distillation temperatures.

Figure 4. Esterification – lower alkyl acrylate process

a) Esterification reactor; b) Ester stripper; c) Bottom stripper; d) Extraction column; e) Light-ends cut column; f) Alcohol-

recovery column; g) Product column

This process for making alkyl acrylates is quite economical because only a small excess of alcohol is applied and the inhibitor is reused; this leads to low energy and inhibitor consumptions. The yield reaches 95 % and 97 % based on acrylic acid and on alcohol, respectively. The purity of the product exceeds 99.5 wt %.

Higher Alkyl Acrylates (see Fig. 5). The esterification reaction is preferably carried out batchwise in the presence of an organic solvent as entrainer and sulfuric acid as catalyst. The water formed is separated through the top of the azeotropic-distillation column (b). The reaction conditions are: atmospheric pressure, temperature 85 – 95°C, reaction time 3 – 5 h, molar ratio (alcohol to acid) 1.0 – 1.1.

After completion of the esterification, the reaction liquid is cooled to 60°C and then transferred to tank (c) where the sulfuric acid is neutralized with alkali. The oil and water layers are separated and stored in tanks d and e, respectively. The oil layer is fed into the solvent-recovery column (f) and subsequently into the alcohol-recovery column (g) for distillation. The solvent and alcohol are recovered overhead and reused in the reaction.

The crude ester obtained from the bottom of the alcohol-recovery column is fed into the product column (h) where purified acrylic ester is obtained by distillation. The bottom liquid mainly is recycled to the reactor and the alcohol-recovery column to be reused as supplementary inhibitor. However, part of the liquid is fed into the bottom stripper (i) to recover valuable materials that are resupplied to the product column. High-boiling waste composed of polymers, inhibitors, and other impurities is taken out of the bottom stripper and incinerated.

The water from the water-layer tank (e) is fed into the organic stripper (j) together with the water layer from the top and the bottom of the solvent-recovery column (f). The oil layer obtained from the top of the solvent-recovery column (f) is recycled into the oil-layer tank. The waste obtained from the bottom of the organic stripper (j) is either treated biologically or incinerated after concentration.

As in the lower alkyl acrylate process, hydroquinone, its monomethyl ether, or phenothiazine is added to each column, and the alcohol-recovery and product columns are operated at reduced pressure.

Figure 5. Esterification – higher alkyl acrylate process

The yield reaches 95 % and 96 % based on acrylic acid and on alcohol, respectively. The purity of the product exceeds 99.5 wt %.

1.4. Quality Specifications and Analysis

Production control requires monitoring the propene and oxygen concentrations in the gas phase of the oxidation. These are checked periodically to maintain optimum reaction conditions and avoid entering the range of flammability. Propene is determined by GLC with flame ionization detection, oxygen by a magnetic meter [71].

The purity of acrylic acid and its esters depends on the production method employed. Table 6 shows quality standards for some of these products. The purity of acrylic acid and its esters is commonly determined from the percentage of impurities measured by GLC with a flame ionization detector. Occasionally the purity of acrylic acid is determined by titration with a base.

Table 6. Quality specifications of acrylic acid and esters[a] [6]

		Acrylic acid		Methyl acrylate	Ethyl acrylate	Butyl acrylate	Octyl acrylate
		99 %	80 %, aq.				
Purity [b]	wt %, min	99.0	80.0	99.0	99.0	99.0	99.0
Acid [c]	wt %, max	–	–	0.005	0.005	0.005	0.005
Water	wt %, max	0.20	–	0.05	0.05	0.05	0.05
Color	APHA, max	20	20	20	20	20	20

Inhibitor [d]	ppm	200	200	15 ± 5	15 ± 5	15 ± 5	15 ± 5

[a] Authorized by the Japanese Acrylic Acid and Esters Industrial Association;
[b] determined by GLC;
[c] as acrylic acid;
[d] as hydroquinone monomethyl ether.

In addition to the purity, the polymerization characteristics are important because acrylic acid and acrylates are used chiefly to make polymers. Polymerization characteristics are determined by examining polymerization patterns such as induction period and temperature elevation under fixed polymerization conditions (temperature, concentration, catalyst, etc.) The degree of polymerization of highly purified acrylic acid is greatly decreased in the presence of trace amounts of heavy metals such as copper, or of aldehydes such as acrolein and furfural.

1.5. Storage and Transportation

Acrylic acid and its esters are usually stabilized with inhibitors such as phenothiazine, hydroquinone, or hydroquinone monomethyl ether. Because phenolic inhibitors are only effective in the presence of oxygen, the monomers must be stored under air (usually normal air for acrylic acid and air with reduced oxygen concentration for esters). The safe handling of these products requires the use of proper protective equipment such as rubber gloves and vapor-proof goggles and masks.

Acrylic Acid. Acrylic acid normally contains 50 to 500 ppm of an inhibitor to prevent polymerization. Because of its relatively high corrosiveness, it should be stored in equipment made of or lined with glass, polyethylene, polypropylene, or stainless steel. In addition, it should be kept at 15 to 30 °C and away from direct sunlight. Freezing should be avoided because it tends to localize the inhibitor. If acrylic acid should freeze, however, it should be melted by using a warm water or air bath below 30 °C. Agitation of the acrylic acid during the melting is recommended to avoid any localized heating. Acrylic acid often is used as an 80 % aqueous solution which has a freezing point of –3 to –5 °C.

Acrylic Esters. In general, a lower level of inhibitor is required for acrylic esters than for the acid, although the range is still 50 to 500 ppm. The esters are less corrosive than the acid and thus can be stored in equipment made of or lined with carbon steel or phenolic resin, in addition to glass, polyethylene, and polypropylene. Grades of acrylates containing little or no inhibitor are available. These products should be carefully stored at temperatures of 0 to 10 °C. Methyl and ethyl acrylates have very low flash points and form explosive gas mixtures in air, even at room temperature. Thus, even though oxygen is an effective inhibitor, the oxygen concentration in large storage tanks is usually kept at 6 to 8 vol % to prevent the formation of a flammable mixture.

1.6. Uses

Acrylic Acid. The primary use of acrylic acid is as an intermediate in the production of acrylates. Polymers of the acid and its sodium salts are used increasingly in flocculants and dispersants with the polymeric sodium salts having more industrial importance (⟶ Polyacrylamides and Poly(Acrylic Acids)).

Acrylic Esters. Acrylic esters are used exclusively for the production of polymers (⟶ Polyacrylates). The polymers are used mainly for coatings, paints, adhesives, and binders for leather, paper, and textiles.

About 80 % of the methyl ester produced is used as a copolymer component of acrylic fibers (⟶). The ethyl ester is used for both solvent- and water-based paints, and in textiles as a binder in nonwoven fabrics and flocking. It generally is used in areas where more rigidity is required than can be obtained with the butyl ester. The butyl ester is growing in use, mainly in water-based paints and adhesives. The 2-ethylhexyl ester is used for almost the same purposes as the butyl ester, with a large demand for it in stick-on labels and in the caulking of building materials.

1.7. Some Special Acrylates

Esters with Polyhydric Alcohols. Representative *multifunctional acrylates* are trimethylolpropane triacrylate, pentaerythritol tri- or tetraacrylate, 1,4-butanediol diacrylate, 1,6-hexanediol diacrylate, and poly(ethylene glycol) diacrylate (n = 2 – 14). They usually are produced by direct esterification of acrylic acid with the corresponding polyhydric alcohol in the presence of an entrainer and an acid catalyst, such as sulfuric acid or *p*-toluenesulfonic acid. Because these esters have high boiling points, they cannot be purified by ordinary distillation. Instead, the reaction mixture is neutralized, the entrainer removed, and the product washed with water [3], [72].

The esters are used as cross-linking agents and modifiers in rubber and synthetic resins, in adhesives, and as active diluents in photosensitive resins. They are also applied in the coating and ink industries because they can be cured with ultraviolet light [73], [74] or electron-beam radiation [75]. Proper protection is required when handling these eye and skin irritants.

2-Hydroxyalkyl Acrylates. Two industrially important multifunctional esters are 2-hydroxyethyl acrylate and 2-hydroxypropyl acrylate. These are produced by liquid-phase esterification of acrylic acid with ethylene oxide or propylene oxide in the presence of a Lewis acid catalyst, such as a chromium [76] or ruthenium [77] compound, or the iron salt of an organic acid [78]. Because this reaction readily produces di(alkylene glycol) monoacrylates and alkylene glycol diacrylates as byproducts, a highly efficient catalyst is required. Although vapor-phase catalytic synthesis using magnesium oxide has been proposed [79], the liquid-phase esterification is preferred. These esters are used especially as cross-linking agents in heat-cured paints, adhesives, textile preparations, etc. They are toxic and lacrimatory, cause blistering of the skin, and may give rise to long-term sensitivity. Inhalation of the vapor causes nose, eye, and throat irritation.

Other Derivatives. Halogenated derivatives such as 2-chloroacrylic acid [80], [81], 2,3-dibromopropyl acrylate [82], tetrafluoropropyl acrylate, and octafluoropentyl acrylate, have potential uses as fine chemicals. Dialkylaminoethyl acrylates are produced by transesterifying methyl acrylate with the corresponding amino alcohol.

1.8. Economic Aspects

Western world production capacities of acrylic acid and its esters as of late 1982 were 839500 t/a and 1277500 t/a, respectively (Table 7). Plants based on other processes, such as the ketene and cyanohydrin methods (see Section Production), were shut down during the past decade because of inefficiency.

Table 7. Estimated regional production capacities for acrylic acid and its esters in the western world (t/a)

	Acid		Esters	
	1982	1994*	1982	1993*
United States	430 000	690 000	700 500	587 000
Western Europe	282 000	640 000	380 000	312 000
Japan	117 500	420 000	182 000	206 000
Others	10 000	–	15 000	–
Total	839 500	ca. 2 000 000	1 277 500	ca. 1 200 00

* [118]

In fact it appears that the propene oxidation route will continue to be the most economical process for quite some time. Announced additional capacities of 280000 and 380000 t/a for the acid and esters, respectively, will all be based on propene oxidation.

Consumption of acrylic acid for uses other than as an intermediate in ester production ranges from 5 to 9 % of the total, although demand for and consumption of both acid and esters varies from region to region. Table 8 gives estimated end-use percentages in three regions. Surface coatings provide the largest market for the esters in all three regions.

Table 8. Estimated distribution of end uses of acrylic esters (% of total)

	United States	Western Europe	Japan
Surface coatings	42	35	34
Textiles	23	18	16
Acrylic fibers	6	7	14
Adhesives	5	15	20
Others	24	25	16

1.9. Toxicology and Occupational Health

Acrylic Acid. Acrylic acid is moderately toxic and very corrosive [84]. Ingestion may cause severe gastrointestinal burns. The vapor is an irritant to the eyes and respiratory tract and skin contact may cause burns. Physiological response data are:

LD_{50} 340 mg/kg (rat, oral)
LC_{50} 3600 mg/m^3 (rat, inhalation, 5 L, 4 h)
LD_{50} 280 mg/kg (rabbit, skin)

The TLV on a time weighted average (TWA) is 10 ppm or 30 mg/m^3.

Acrylic Esters. Acrylic esters are of moderately acute toxicity, which decreases with an increase in the number of carbon atoms in the alkyl group (Table 9). Liquid methyl and ethyl acrylates severely irritate the skin and mucous membranes and are corrosive to the eyes, whereas the butyl and 2-ethylhexyl acrylates have less severe effects. Methyl and ethyl acrylate vapors are very lacrimatory, extremely irritating to the respiratory tract, and are corrosive to the eyes, causing corneal injury. The lacrimatory effect of the butyl and 2-ethylhexyl esters is weak, but their vapors may cause dizziness, headache, nausea, and vomiting.

Table 9. Physiological response data and exposure levels of some acrylates

	Methyl acrylate	Ethyl acrylate	Butyl acrylate	2-Ethylhexyl acrylate
LD_{50} (rat, oral), mg/kg	300	1020	3730	5660
LCLo (rat, inhalation, 4 h),	3500	4000	5500	

mg/m^3				
LD_{50} (rabbit, dermal), mg/kg	1243	1950	2000	8480
TLV (TWA)	10 ppm, 35 mg/m^3	5 ppm, ≈ 20 mg/m^3	10 ppm, 55 mg/m^3	
MAK	10 ppm, 35 mg/m^3	25 ppm, 100 mg/m^3		

Methyl and ethyl acrylates can be absorbed through the skin in toxic amounts, and overexposure to the vapor can result in fatal pulmonary edema. However, their noticeable odors and irritating effects reduce the likelihood of significant exposure.

[Top of Page]

2. Cyanoacrylates

Klaus Marten

The monofunctional 2-cyanoacrylates, CH_2 = C(CN)-COOR, have been known for many years. Technical developments, based on the original patents of 1949 [85], led in 1954 to the first viable production process [86], [87]. Since then these compounds have achieved a considerable growth rate on the market. The 2-cyanoacrylates are utilized almost exclusively as adhesives. The methyl, ethyl, butyl, allyl, and methoxyethyl esters are available with different setting characteristics and rheological properties, depending on the requirements of the application.

Physical Properties. Pure 2-cyanoacrylates are clear, colorless liquids at room temperature and have a characteristic odor. Their physical properties are listed in Table 10.

Table 10. Physical properties of industrially important 2-cyanoacrylates

Property	Methyl	Ethyl	Butyl	Allyl	Methoxyethyl
CAS registry number	[137-05-3]	[7085-85-0]	[6606-65-1]	[7324-02-9]	[27816-23-5]
Molecular formula	$C_5H_5NO_2$	$C_6H_7NO_2$	$C_8H_{11}NO_2$	$C_7H_7NO_2$	$C_7H_9NO_3$

Vapor pressure at 25 °C, kPa	<0.27	<0.27	<0.27	–	–

Chemical Properties. The vinyl structure of the 2-cyanoacrylates makes them liable to spontaneous polymerization. This is desirable for their use as reactive adhesives, but causes significant difficulties in synthesizing and especially in purifying them.

Because the chain propagation reaction can be initiated by either an ionic or a radical mechanism, the rate of polymerization depends on temperature, humidity, light, and the presence of polymerization accelerators, such as peroxides and bases. The 2-cyanoacrylates are, however, adequately stable if stored under cool conditions in the presence of suitable inhibitors. In addition to polymerization, they undergo the other reactions typical of vinyl compounds (e.g., addition).

Production. Many different processes can be used to manufacture 2-cyanoacrylates. The important step in most of the published syntheses is the classical Knoevenagel reaction using formaldehyde and a cyanoacetic ester. In this first step oligomeric cyanoacrylates, water, and other byproducts are formed. The reaction can be catalyzed by bases (e.g., amines) [86], [87], alkali metal tetraborates, metal carbonyls [89], or phase-transfer catalysts [90]. The raw condensation product from

the first reaction is depolymerized thermally (either continuously or discontinuously) [91] and purified by distillation, chromatography on alumina or silica gel [92], crystallization in polyethylene columns [93], or treatment with zinc chloride [94].

Alternatively, 2-cyanoacrylates can be manufactured by the ethoxycarbonylation of cyanoacetylene in the presence of nickel carbonyl [95].

Uses. 2-Cyanoacrylate-based formulations have been a valuable component of modern adhesive technology for many years. Their ability to join the most dissimilar materials quickly, firmly, and durably has insured a wide field of applications. They are used in the electrical and electronics industries as well as many areas of mechanical engineering, such as automobile, ship, and aircraft construction. In addition to these purely technical applications, the 2-cyanoacrylates are used in medicine to close wounds.

Special properties to meet specific requirements are obtained by the use of additives or a manufacturer's proprietary process. Such parameters as hardening time [96-98], viscosity [99], [100], relative strength [101], resistance to hydrolysis [102], [103], heat resistance [104], [105], flexibility of the mature adhesive [106], [107], and shelf life [108-110] commonly are varied (⟶ Adhesives).

Toxicology and Occupational Health. Both the MAK and the TLV exposure limits for 2-cyanoacrylates have been set at 2 ppm. Adequate ventilation of the work place is therefore necessary if these substances are in continual use. Further information can be obtained from the relevant documentation provided by suppliers. Although many years of practical use have not yet led to any significant damage to health, the toxicology of 2-cyanoacrylates requires further investigation [111], [112]

[Top of Page]

3. Acrylamide

Helmut Greim

Properties. Acrylamide [79-06-1], 2-propenamide, $CH_2 = CHCONH_2$, M_r 71.08, *mp* 84.5 °C, usually forms white crystalline platelets. It is very toxic.

Acrylamide is most conveniently handled as an aqueous solution because the dry powder forms a fine, toxic dust. It is soluble in water, alcohols, and acetone but insoluble in benzene and heptane.

Acrylamide and polyacrylamide can be converted into various products by the usual addition reactions of the double bond and especially by reactions of the amide group:

$$\begin{aligned}
RCONH_2 + HCHO &\longrightarrow RCONHCH_2OH \\
+ 2\,HCHO &\longrightarrow RCON(CH_2OH)_2 \\
2\,RCONH_2 + HCHO &\longrightarrow (RCONH)_2CH_2 \\
RCONH_2 + HCHO + NaHSO_3 &\longrightarrow \\
& \qquad RCONH-CH_2SO_3Na + H_2O \\
+ HCHO + R'R''NH &\longrightarrow \\
& \qquad RCONH-CH_2NHR'R'' + H_2O \\
+ NaOCl + 2\,NaOH &\longrightarrow \\
& \qquad RNH_2 + Na_2CO_3 + NaCl + H_2O \\
+ H_2N-NR'R'' &\longrightarrow RCONH-NR'R'' + NH_3
\end{aligned}$$

N-Alkyl derivatives of acrylamide are prepared by the reaction of acryloyl chloride with the corresponding amine, by the dehydrochlorination of 2-chloropropionamide, or by the amination of acrylic acid or esters [113].

Production. Acrylamide was first produced on a large scale, by American Cyanamid, in 1954. It is currently produced from acrylonitrile either by homogeneous sulfuric acid hydration or by heterogeneous catalytic hydration.

Sulfuric Acid Process. One mole of Acrylonitrile (⟶ Acrylonitrile) is added to a solution of 1 mol sulfuric acid and 1 mol of water at 60 °C. The mixture is slowly heated to 80 °C, kept for an hour at this temperature, and then cooled to 40 °C. Ammonium sulfate precipitates on neutralization with ammonia and is filtered out. The acrylamide, which crystallizes on cooling the mother liquor to below 10 °C, is purified by recrystallization from benzene.

Catalytic Hydration Process. Figure 6 shows a flow diagram of this process. A 50 wt % solution of acrylonitrile in water is slurried with a catalyst such as Raney copper and kept at 120 °C for 2.5 h. Conversion of acrylonitrile is greater than 50 % and selectivity to the amide is nearly 100 %. This process conveniently makes an aqueous solution of 30 to 50 wt % acrylamide because of the large amount of water required in the reaction.

Figure 6. Catalytic hydration of acrylonitrile

Biological Process. A patented biocatalyst enables the hydration of acrylonitrile at room temperature and pressure in a process developed by Nitto Chemical Industry Co. (Tokyo). The catalyst is an enzyme derived from one of several bacterial genera [114].

Uses. Acrylamide is made mainly into water-soluble polymers and copolymers used in flocculants, papermaking aids, thickening agents, surface coatings, and enhanced oil recovery [113], [115] (⟶ Polyacrylamides and Poly(Acrylic Acids)).

Toxicology and Occupational Health. The health consequences of human exposure to acrylamide have been repeatedly evaluated [118-122]. Most of the information given in the following is derived from these reports in addition to more recent scientific publications.

Effects Assessment. In humans and laboratory animals, single or repeated exposures to acrylamide caused local irritations on contact with the skin and neurological symptoms. The peripheral neuropathy is a result of long-term accumulation and appears after a latent period. Its onset parallels the accumulation of acrylamide bound to proteins in the nervous system and to hemoglobin. In a two year's study in rats exposed to acrylamide via drinking water the lowest observed effect level (LOEL) for peripheral neuropathy was 0.5 mg/kg.

Acrylamide is readily absorbed during oral, inhalation and dermal exposure. In rats the major route of metabolism is direct conjugation with glutathione and subsequent urinary excretion of the conjugate. The compound is also metabolized by cytochrome P-450 2E1 dependent monooxygenase activity forming the epoxide glycidamide [123].

Both, acrylamide and glycidamide interact with proteins and form hemoglobin adducts. Glycidamide interacts with DNA and is considered the genotoxic and carcinogenic intermediate. Mice form more glycidamide than rats and there is an indication that humans form less glycidamide than rats. These species differences in metabolism explain the lower potency to induce tumors in rats than in mice and suggest that humans are less sensitive than rats.

In rats acrylamide induced increased incidences of thyroid adenomas, testicular mesotheliomas, adrenal phaeochromocytomas, fibroadenomas in the mammary gland, and focal hyperplasia in the oral cavity. An increased incidence of astrocytomas was also detected. The lowest effective dose in these studies was 1–2 mg/kg bw/da. (mg per kilogram body weight and day).

In mice skin painting experiments acrylamide initiates the formation of skin tumors. Epidemiological studies have not revealed tumors in humans. Since the carcinogenic potency of acrylamide in animals is weak the epidemiological studies may not be sensitive enough to show an increased tumor incidence in man.

Acrylamide is considered to be genotoxic although contradictory results have been obtained in the various assays. In bacterial systems glycidamide but not acrylamide induced mutations. In mammalian cells in vitro chromosomal aberrations, micronuclei, sister chromatid exchanges, polyploidy and other cytogenetic effects have been observed. In vivo the compound was positive in the bone marrow chromosome aberration test and in the micronucleus assay.

Overall, the long term animal studies, its genotoxicity, and the formation of the genotoxic metabolite glycidamide in humans indicate that acrylamide has the potential to cause cancer in humans. Accordingly, IARC, the EU, and several national committees classified acrylamide as probably carcinogenic to humans.

In reproductive toxicity studies with rats, the no observed adverse effect level (NOAEL) for reduced fertility was 5 mg/kg bw/da and for premature embryonic death 2 mg/kg bw/da.

Exposure. The concern in 2002 is the relatively high exposure of consumers from fried, oven-baked, and deep-fried potato and cereal foods. The Scientific Committee on Food of the European Commission [124] estimates an average daily human intake of about 1 µg/kg considering that differently contaminated food, some of which containing up to 3000 µg acrylamide per kilogram, is consumed. Contamination of certain food had been first detected by the Swedish National Food Agency. They found that especially potato products such as chips and crisps, but also basic staple foods such as bread and crisp bread contained varying high levels of acrylamide. Acrylamide was not detected in boiled foods. These results have been confirmed by analyses of foods in other European countries.

The available information suggests that acrylamide is primarily formed in carbohydrate-rich foods at high temperatures. It is presently being evaluated whether changes in food processing and cooking may decrease formation of acrylamide.

At the workplace exposure occurs during acrylamide and polyacrylamide production, during grouting and during preparation of polyacrylamide gels. Low levels have been detected in the drinking water from the use of polyacrylamide flocculants in water treatment and from the use of polyacrylamides in cosmetics and toiletries [122].

Risk Characterization. The available information indicates that there are concerns regarding neurotoxicity (NOEL 0.5 mg/kg bw/da), impact on the reproduction system (NOEL 2 mg/kg bw/da) and carcinogenicity. Based on the average daily intake by

humans via food of 1 µg/kg bw/da the margin of safety (MOS) between this exposure and the NOEL of neurotoxicity is 500.

Due to its genotoxic potential no dose threshold for the carcinogenic effect of acrylamide can be established. Using a linear extrapolation from the carcinogenicity studies in animals the lifetime cancer risk related to a daily intake for 70 years of 1 µg/kg acrylamide is about 1×10^{-3} (one case of cancer per 1000 individuals).

The TLV-TWA is 0.03 mg/m^3 with a skin notation without a STEL, A3: confirmed animal carcinogen. The TRK (Technische Richtkonzentration) is 0.06 mg/m^3. Classification of acrylamide by IARC: probable carcinogen for humans (2b), MAK: Considered to be carcinogenic to man (Cat. 2).

1. Introduction

In 1893, the French chemist, Ch. Moureau, first prepared acrylonitrile [107-13-1], acrylic acid nitrile, propene nitrile, vinyl cyanide, CH_2=CH-C≡N, M_r 53.06, by dehydrating either acrylamide or ethylene cyanohydrin with phosphorus pentoxide [1]. However, no significant technical or commercial applications were discovered for acrylonitrile until the late 1930s.

Shortly before the Second World War, I. G. Farbenindustrie introduced a synthetic rubber, Buna N, based on a copolymer of butadiene and acrylonitrile. This synthetic rubber was highly resistant to swelling in gasoline, oils, and other nonpolar solvents. At about the same time research began in the United States on similar copolymers termed GR-A, NBR, or nitrile rubber. Projects con-

as end-use products of acrylonitrile in the United States and Japan. Adiponitrile is further converted to hexamethylenediamine (HMDA), used to manufacture nylon 66 (→ Hexamethylenediamine). Acrylamide is used to produce water-soluble polymers or copolymers used for paper manufacturing, waste treatment, mining applications, and enhanced oil recovery.

Nitrile rubbers, the original driving force behind acrylonitrile production, have taken a less significant place as end-use products. They find industrial applications in areas where their oil resistance and low-temperature flexibility are important, such as in the fabrication of seals (O-rings), fuel hoses, and oil well equipment.

In the future, acrylonitrile may be used increasingly for such things as high-nitrile barrier resins

1. Introduction

Alkylation and acylation can be defined as the introduction of an alkyl (R) or an acyl (RCO) group, respectively, into a molecule. These two types of reaction have many features in common. For instance, essentially the same catalysts can be applied, leading to related reaction intermediates. The definition given above covers a wide range of reactions. Although alkylations and acylations often are referred to as acid-catalyzed Friedel – Crafts-type reactions only, alkylation can refer also to the preparation of alkylates in refinery operations. In this article, the major emphasis is on industrial significance; reactions are classified according to substrate type.

Because alkylation and acylation reactions are diverse in nature, there is no universal method of carrying them out. The production of each compound must be considered individually, assessing chemical, engineering, and economic factors.

Industrial Importance. A variety of acylations and alkylations are carried out on a large industrial scale. Some reactions of this type are used predominantly for the synthesis of fine chemicals, such as pharmaceuticals or agricultural chemicals. Some of the processes used

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a01_185

to produce large-volume chemicals are summarized in Table 1, underlining their commercial value. Further examples are given in the relevant subchapters.

1.1. Catalysts

Although alkylations can be carried out thermally by free-radical pathways, all commercial alkylation and acylation processes are conducted using acidic, basic, or organometallic compounds as promoters. These promoters function by increasing either the nucleophilicity of the substrate (*basic catalysis*) or the electrophilic character of the reagent (*acidic catalysis*).

1.1.1. Acidic Catalysts

The acidic catalysts can be divided into five groups: acidic halides, metal alkyls and alkoxides, proton acids, acidic oxides and sulfides, supported acids and cation-exchange resins.

Acidic Halides. All Lewis acids, including the metal halides known as Friedel – Crafts catalysts, have an electron-deficient center capable of attracting electrons from the basic reagents. Olah has classified the catalytic activity of a variety of halide Lewis acids for the alkylation of benzene or toluene by benzyl chloride [13]. Catalysts of the highest activity give rise to intra- and intermolecular isomerization reactions as well as the desired alkylation. Therefore, depending on the alkylating agent, the substrate, and the reaction conditions, the choice of the catalysts has to be a compromise between activity and product selectivity. The acidic halide catalysts most frequently used are aluminum chloride and aluminum bromide. Other common catalysts are BF_3, BCl_3, BBr_3, $BeCl_2$, $CdCl_2$, $ZnCl_2$, $GaCl_3$, $GaBr_3$, $FeCl_3$, $SbCl_3$, $BiCl_3$, $TiCl_4$, $ZrCl_4$, $SnCl_4$, UCl_4, and $SbCl_5$. In industrial applications, however, aluminum chloride is the catalyst of choice because of its low cost and wide availability.

In their original work, Friedel and Crafts described reactions using anhydrous aluminum chloride. However, it is rather difficult to obtain aluminum chloride or other Lewis acid-type metal halides in an absolutely anhydrous state. Even if this were possible, contamination, for example, moisture during application to a reaction mixture, is extremely difficult to exclude completely. Therefore, under the usual Friedel – Crafts conditions, the presence of such impurities as water, oxygen, hydrogen halides, or organic halides is inevitable. Fortunately, these compounds are beneficial in trace amounts and in many cases they are even essential cocatalysts [14]. These cocatalysts can be proton suppliers, such as hydroxy compounds (alcohols, water) and proton acids (HCl, H_2SO_4, H_3PO_4, RCOOH), leading to very strong conjugated proton acids:

$$HX + AlX_3 \rightleftharpoons H^+AlX_4^-$$

Cation-forming compounds, such as alkyl and acyl halides or oxygen, nitrogen, sulfur, and halide donors, also are effective promoters.

From an environmental point of view, acid halides have the disadvantage to produce waste salts after work-up/neutralization of the product mixture. In an effort to minimize waste formation, reusable aluminum catalysts have been developed. The catalyst forms a liquid clathrate which is insoluble in the Friedel – Crafts reaction products, is separated, e.g., by phase separation, and is recycled to the process [15].

Ionic Liquids. A promising new development is the use of ionic liquids as catalysts and solvents for alkylations and acylations. Chloroaluminate(III) liquids, that form ionic liquids at room temperature, specifically 1-butylpyridinium chloride – aluminum(III) chloride and 1-butyl-3-methylimidazolium chloride – aluminum(III) chloride, allow separation of products from catalysts and provide access to a clean technology, where formation of large amounts of salts as the byproduct is avoided. The design principles for room-temperature ionic liquids, some of their properties, and the rationale for using these neoteric solvents, are discussed in [16] and an indication of the scope of these solvents for future industrial processes is given.

Metal Alkyls and Alkoxides. Because of their Lewis acidity, metal alkyls and alkoxides are active catalysts in Friedel – Crafts reactions. However, the Lewis acidity in these systems,

Table 1. Examples of industrial alkylation processes

Reaction type	Process description		Production, 10^6 t/a ∗
Alkylation of aromatics			
Benzene and ethylene to give ethylbenzene	a)	liquid phase, 85 – 95 °C, 1 bar, catalyst: $AlCl_3$ (BASF, Dow), zeolites (Lummus/Unocal/UOP), MCM-22 zeolite (EBMax, Mobil)	20
	b)	vapor phase, 250 – 450 °C, 10 – 80 bar, catalyst: $Al_2O_3 \cdot SiO_2$ (Koppers), $H_3PO_4 - SiO_2$ (UOP), $BF_3 - Al_2O_3$ (UOP, Alkar process), zeolites ZSM-5 (Mobil/Badger)	
Benzene and propene to give cumene	a)	liquid phase, 35 – 70 °C, 5 – 15 bar, catalyst: solid phosphoric acid (UOP), $AlCl_3$ catalyst (Monsanto/Kellog), H_2SO_4 (Hock process), HF (Hüls)	7.5
	b)	zeolite technologies (Mobil, UOP – QMax, CDTech, Dow/Kellog and Enichem)	
Benzene and propene to give *p*-diisopropylbenzene		liquid phase, 150 – 250 °C, 1 bar, catalyst: $Al_2O_3 \cdot SiO_2$ (Shell), zeolites	0.1
Benzene and $C_{10} - C_{18}$ olefins (or alkyl chlorides) to give alkylbenzenes		liquid phase, 10 – 80 °C, 1 bar, catalyst: HF, H_2SO_4, $AlCl_3$, fluorided silica – alumina, UOP-Detal	0.9
Alkylation of phenols			
Phenol and $C_6 - C_{20}$ olefins to give alkylphenols	a)	liquid phase, 20 – 100 °C, 1 – 20 bar, catalyst: BF_3 , H_2SO_4 , H_3PO_4 – support, cation-exchange resins	
	b)	vapor phase, 300 – 400 °C, 1 – 30 bar, catalyst: BF_3 – support, H_3PO_4 – support, $Al_2O_3 \cdot SiO_2$	0.3
Phenol and methanol to give *o*-cresol		liquid phase, 300 – 360 °C, 40 – 70 bar, catalyst: $Al_2O_3 \cdot SiO_2$, $ZnBr_2$ – HBr	–
Phenol and acetone to give bisphenol A		50 °C, catalyst: H_2SO_4, HCl, cation-exchange resins	1.1
N-Alkylation			
Ammonia and methanol to give methylamines		350 – 400 °C, catalyst: $Al_2O_3 \cdot SiO_2$, H_3PO_4 – support	0.6
O-Alkylation			
Methanol and isobutene to give methyl *tert*-butyl ether		$<$100 °C, catalyst: anion-exchange resins	0.12
Metal alkylation			
Na/Pb alloy and RCl to give PbR_4		70 °C, no catalyst	0.6

∗ estimated for 1992.

particularly for metal alkoxides, is weakened by hyperconjugation effects. Nevertheless, an important industrial application is the alkylation of phenols, in which aluminum phenoxide is used as the catalyst. Again, a conjugated acid is believed to be the active catalyst:

$$C_6H_5OH + Al(OC_6H_5)_3 \rightleftharpoons H^+Al(OC_6H_5)_4^-$$

Aluminum metal can form aluminum phenoxide in phenolic solution.

Rare Earth Metal Trifluoromethansulfonates (Triflates). This type of catalyst can be recycled after use and avoids the stoichiometric formation of metal salts as is the case with conventional homogeneous promoters.

Proton Acids. A variety of proton acids can be used in Friedel – Crafts alkylations, the most important examples being sulfuric acid, anhydrous hydrogen fluoride, trifluoroacetic acid, hydrogen chloride, and phosphoric acids [17]. Combinations of Lewis acids and proton acids, such as $HCl - AlCl_3$, $HCl - GaCl_3$, $HF - BF_3$, $H_2SO_4 - BF_3$, and $HF - SbF_5$, also can be applied and these act as conjugate proton superacids [18], [19]. Similarly, most Lewis acids work under industrial conditions, where traces of moisture or of other proton donors cannot be excluded.

Acidic Oxides and Derivatives. Solid catalysts are progressively substituting liquid acid catalysts in oil refining and synthesis of large

volume chemicals. This development is due to novel environmental legislation as well as economic advantages resulting from superior product qualities of solid catalysts and the possibility to work under noncorrosive conditions (facile construction, handling and disposal). Solid catalysts are generally classified into different groups, i.e., zeolites, mixed oxides, or solid superacids (e.g., sulfated oxides), clays, heteropolyacids or polyoxoanions, supported acids, and cation-exchange resins. The latter two will be discussed in page 4 and page 4

Zeolites (→ Zeolites) represent a class of acidic (or basic) microporous materials with a defined pore structure. The most widely used systems are based on silica and alumina, however, a large variety of other elements have been integrated into the zeolite framework. For a comprehensive review on zeolite types see [20]. Acidity in zeolites is generated by Brønsted and Lewis acid sites. The former are attributed to protons compensating for the negative lattice charge of an oxygen atom in vicinity to an aluminum atom, the latter are believed to result from lattice defect sites and/or extra-framework aluminum species. Zeolites are thermally stable up to 800 °C allowing high-temperature reactions and the thermal regeneration of spent catalysts by burning the carbonaceous residues in oxygen-containing gas streams. Zeolites can be synthesized in a wide variety of pore sizes. Number and strength of Brønsted acid sites as well as crystal sizes may be tuned. The versatility of these materials lead, thus, to a broad field of industrial applications, e.g., fluid catalytic cracking (FCC), alkylation, aromatization, isomerization, and oligomerization [21].

Mixed oxides represent probably the largest group of solid acid catalysts. Various mixtures of (doped) metal oxides have been investigated in acid catalyzed reactions. Excellent reviews were provided by Arata [22] and Tanabe [23–25]. As with zeolites, acidity is generated by the incorporation of heteroatoms (different valence) in a crystal-lattice structure. Some of these materials are quoted superacids due to the presence of acid sites stronger than 100 % H_2SO_4 ($H_0 < -12$) [H_0 = Hammelt acidity function, where $H_0 = pk_a$ (indicator) + log ($c_{\mathrm{indicator}}/c_{\mathrm{H[indicator]+}}$)].

Clays. Natural clays have attracted relatively low attention, however, pillaring those materials with interlayer anions yields porous materials similar to zeolites. Although those materials have been described to be useful for alkylation, especially for larger molecules [26], [27], little is known about their industrial application in alkylation reactions. Generally, the thermal stability and chemical resistance is much smaller than that of zeolites.

Heteropolyacids or polyoxoanion compounds constitute a large category of coordination-type salts and free acids with each member containing a complex and high molecular mass anion. In these anions, two to eighteen hexavalent molybdenum (or tungsten) atoms surround one or more central atoms (heteroatom). Vanadium, niobium, tantalum, and transition metals can replace some of the molybdenum (or tungsten) atoms in the heteropoly structure. Typical examples are $[PMo_{12}O_{40}]^{3-}$, $[SiW_{12}O_{40}]^{4-}$, $[PMo_{10}V_2O_{40}]^{5-}$. An excellent review was given in [28]. As with clays, little is known about the commercialization of these materials in alkylation reactions.

Supported Acids. A variety of fixed-bed processes have been commercialized in which Lewis or Brønsted acids are supported on alumina, silica, or various other supports (e.g., carbon, graphite). A widely used catalyst of this type is "solid phosphoric acid" (phosporic acid adsorbed on kieselguhr), used for the alkylation of benzene with ethylene, butenes, and cyclohexene, but especially with propene. During use, the catalyst loses water which controls the equilibrium between ortho, meta, and poly phosphoric acid and hence catalytic activity. Small amounts (≦0.1 % of feed) of water or of the corresponding alcohol (e.g., isopropyl alcohol for the production of cumene) therefore are added to the reaction mixture in order to regenerate the catalyst and thus maintain activity [29]. Other examples of supported acids are boron trifluoride – alumina and solid superacids, such as SbF_5, TaF_5, and NbF_5, supported on fluorinated alumina or graphite. Graphite-intercalated $AlCl_3$ (i.e., $AlCl_3$ embedded in graphite) also is an effective solid Friedel – Crafts catalyst but loses activity by partial hydrolysis or leaching of the Lewis acid halide from the graphite [30]. Furthermore, Lewis-acidic metal halides supported on layered clays have attracted attention as heterogeneous catalysts.

Cation-Exchange Resins. *Solid Brønsted acids,* such as sulfonated styrene – divinylbenzene cross-linked polymers, are used as an acidic catalyst in a variety of organic reactions. *Cation-exchange resins,* such as Permutit Q, Lewatit, and Dowex 50, are effective catalysts for the alkylation of phenols with olefins, alkyl halides, and alcohols [31]. Catalysts of this type also have been applied in the acylation of thiophene with acetyl chloride or acetic anhydride [32]. Perfluorinated resin sulfonic acids, such as the acid form of DuPont's Nafion, catalyze many alkylations of aromatic hydrocarbons very efficiently [33], [34]. New developments in this field are DuPont's Nafion – silica nanocomposite [35] and Degussa's Deloxan materials [36].

1.1.2. Basic Catalysts

Basic catalysts are preferred for C-alkylations and C-acylations of CH acidic compounds. Here, the base increases the nucleophilicity of the CH acidic compound. The type of catalyst depends upon the substrate to be alkylated or acylated. Often, the compounds are of such low acidity that prior formation of a metal derivative is required. Aliphatic compounds with electron-attracting substituents, for example, CN or CO, usually are depronated by alkoxide, amide, and similar ions:

$$RCH_2CN + NH_2^- \longrightarrow R^{\ominus}CHCN + NH_3$$

$$RCH_2CN + OH^- \longrightarrow R^{\ominus}CHCN + H_2O$$

Commonly used bases include sodium alkoxides, sodium amide, and sodium hydride. Sometimes the powerful triphenylmethylsodium (tritylsodium) or even alkali metals (for example, Na in liquid NH_3 [37] or Na supported on γ-Al_2O_3 [38]) must be used. For example, toluene is alkylated with ethylene or propene to give propylbenzene or isobutylbenzene and cumene is alkylated with ethylene to give (1,1-dimethyl)propylbenzene.

Reactions catalyzed by mild bases were conducted on a wide variety of basic oxides (MgO, ZrO_2, La_2O_3) and basic microporous materials. The side-chain alkylation of toluene with methanol, aldol condensations, Knoevenagel reactions, and Michael additions represent the most common reactions of this type described in literature. A review on basic zeolites was provided in [39].

1.1.3. Organometallic Catalysts [40], [41]

A variety of catalysts based on transition-metal compounds are known in alkylation and acylation, as in the following examples (R,R′ = alkyl, L = $(C_6H_5)_3P$):

As yet, these catalysts are of no major industrial importance and therefore are not discussed further.

1.2. Alkylating and Acylating Agents

The most widely used alkylating agents are olefins and alkyl halides. The most important olefins are ethylene, propene, dodecene (tetrapropene), and linear olefins with 10 – 20 carbon atoms; all are used in large-scale industrial alkylation processes. Among the alkyl halides, methyl chloride, methyl iodide, ethyl chloride, isopropyl chloride, *tert*-butyl chloride, and benzyl chloride often are used.

Alcohols, ethers, esters of inorganic or organic acids, epoxides, aldehydes and ketones, thiols, and related compounds can be used, but in these cases more than catalytic amounts of the Lewis acid usually are required because the catalyst partly hydrolyzes.

Other powerful alkylating agents are dimethyl sulfate, diethyl sulfate, ethyl *p*-toluenesulfonate, trifluoromethanesulfonic acid, its methyl or ethyl ester, as well as aliphatic diazo compounds and triethyloxonium tetrafluoroborate [*368-39-8*]. Alkylating agents, especially

those of the last group, may present a health hazard.

The acylating agents most frequently used are acyl halides, carboxylic acids, and anhydrides. Less frequently used are ketenes, esters, lactones, etc. Amides [42] and phosgene also can function as acylating agents.

1.3. Mechanism

The majority of industrial alkylations and acylations are acid catalyzed (Friedel – Crafts type). Therefore only these processes are considered here. Both alkylation and acylation can proceed via similar reaction intermediates, involving similar reaction mechanisms.

1.3.1. Alkylation

Friedel – Crafts alkylation is induced by interaction of the acidic catalyst with the alkylating agent, as exemplified below for $AlCl_3$, leading to the formation of a highly polarized complex containing a carbocation:

$$R\text{-}CH{=}CH_2 + HX + AlX_3 \rightleftharpoons [R\text{-}HC^{\oplus}\text{-}CH_3][AlX_4]^-$$

$$RX + AlX_3 \rightleftharpoons [R]^+[AlX_4]^-$$

$$ROH + AlX_3 \rightleftharpoons [R]^+[AlX_3OH]^-$$

R = alkyl

In the case of alkyl halides, carbocations are formed in the complete absence of moisture or any proton acid, whereas in the case of olefins a proton donor is needed. The carbocation then attacks the aromatic substrate, forming the intermediate (**1**), which is transformed into the product by loss of a proton [43]:

Under the acidic conditions used, both the alkylating agent and the alkylated aromatic compound isomerize. This leads in many cases to a situation in which neither the structure of the alkyl substituent nor the orientation in the nucleus can be predicted.

Friedel – Crafts reactions do not necessarily require free carbenium ions as intermediates; the reaction can proceed also via formation of a polarized complex between the Lewis acid and the alkylating agent followed by attack of the aromatic substrate [44]. However, carbocationic intermediates as postulated in Friedel – Crafts reactions were observed in superacidic media and were studied by spectroscopic methods [45].

Alkylation on Solid Acids. The mechanism of alkylation of aromatics on solid acid catalysts (especially on zeolites) has been reviewed by Venuto [46]. Briefly, alkylation involves an electrophilic addition of a carbocation (formed through protonation of or hydride abstraction from the alkylating agent) to the aromatic ring. However, depending on the basicity of the aromatic ring compared to that of the alkylating agent and depending on temperature either the aromatic ring or the olefin is preferentially adsorbed on the acid sites and thus, forms the carbocation [47]. Although many different heterogeneous catalysts may be used, a major benefit of microporous materials is offered by their shape selectivity. Three different types of shape selective effects have been postulated, i.e., (1) reactant selectivity, (2) transition state selectivity, and (3) product selectivity. Since the pore size of zeolites and the kinetic diameter of the reacting molecules are in the same order of magnitude, bulky isomers/molecules are selectively prevented to (1) enter the zeolite channels, (2) to be produced in the transition state, or (3) to leave the zeolite pores. Commercialized processes using this concept are, e.g., Mobil's Selective Toluene Disproportionation Process (MSTDP) or Mobil's xylene isomerization, both using ZSM-5 zeolites. In the former process, toluene is disproportionated to *p*-xylene and benzene; *m*- and *o*-xylene are produced in minor amounts due to diffusion limitations in the zeolite channels. Mobil/Badger's gas-phase

EB process using a ZSM-5 zeolite and UOP's Q-Max cumene process as well as many other commercial processes (see below) avoid the formation of polysubstituted aromatics effectively due to shape selectivity. A comprehensive review on the industrial application of shape selective catalysis was given by CHEN and GARWOOD [48].

1.3.2. Acylation

The mechanistic features of acylation can be illustrated by the reaction of an acyl halide with an aromatic substrate using $AlCl_3$ as the catalyst. The reaction of the acyl halide with the Lewis acid leads to a more or less polarized complex or even an acylium ion, both of which can act as the active electrophile as shown below [49] (R = alkyl, aryl):

The formation of significant amounts of the free acylium ion can be expected only in highly polar solvents, such as nitrobenzene or nitromethane. The acylium ion mechanism is also favored if steric hindrance occurs either in the acylating compound or in the aromatic substrate [49]. Also, if anhydrides, esters, or the carbonic acids themselves are used as the acylating agents in the presence of proton acids, a high concentration of acylium ions can be expected.

2. Alkylation and Acylation of Aromatic Compounds

The acid-catalyzed conversion of aromatic compounds to their alkylated or acylated derivatives was discovered as early as 1877 by FRIEDEL and CRAFTS. Using anhydrous aluminum trichloride as catalyst, they were able to demonstrate the reactivity of aromatic hydrocarbons toward organic halides and unsaturated compounds, organic acid anhydrides, phosgene, carbon dioxide, and other compounds. Several important industrial processes then emerged, including the synthesis of ethylbenzene, cumene, higher alkylbenzenes, alkylphenols, benzophenone, and anthraquinone. These compounds have found broad application in the production of polymers, detergents, perfumes, pharmaceuticals, dyes, and agricultural chemicals.

2.1. Alkylation

The Friedel – Crafts alkylation of aromatic compounds is an acid-catalyzed electrophilic substitution of an aromatic hydrogen by an alkyl group. A variety of alkylating agents can be used, but typically olefins, alkyl halides, and alcohols are applied. All aromatic substrates accessible to electrophilic substitution can be used, including heteroaromatic compounds and such compounds as ferrocene. These fast, exothermic reactions usually are carried out under mild conditions in the liquid phase, although, for some substrates, vapor-phase processes with more stringent conditions are applied. Using olefins, alkyl halides, and alcohols as alkylating agents, the following overall reactions occur:

Depending on the acidity of the catalyst, the alkyl moiety is more or less completely isomerized, and the addition follows the Markovnikov rule.

Catalysts for Friedel – Crafts alkylation must be acidic. Depending on reaction conditions, alkylating agents, and aromatic substrates, Lewis as well as Brønsted acids are active. Table 2 lists frequently used catalysts and classifies them on the basis of chemical constitutions.

Although acidic halides, such as $AlCl_3$ or $AlBr_3$, and proton acids, such as HCl, HF, or H_2SO_4, or H_3PO_4 supported on diatomaceous earth are widely used, those catalysts are being progressively substituted by zeolites and inorganic oxides because the latter are environmentally benign, easy to handle and to dispose, thus implying less expensive process design.

All types of bases reduce the acidity of the catalyst and hence its efficiency. This is especially true for organic nitrogen compounds. Heavy resinous materials are formed on the catalyst if oxygen is present even at concentrations as low as 20 ppm [50]. Dienes, such as butadiene in a butene feed, also cause the formation of resinous or tarry materials on the catalyst. Traces of moisture or other proton suppliers in many cases enhance catalytic activity, especially of Lewis acids. Higher amounts of these compounds are detrimental to the catalyst. Therefore, it is not surprising that when alcohols are used, for example, for the alkylation of benzene, 0.5 – 1.0 mol $AlCl_3$ per mole of alcohol is necessary because the water produced reacts with the Lewis acid. In some cases, mild catalyst poisons are used deliberately in order to lower catalyst acidity and to prevent side reactions, such as isomerization. Typical examples are organic nitro compounds, which form stoichiometric complexes with Lewis acids. Compounds such as $AlCl_3 \cdot RNO_2$, $AlBr_3 \cdot RNO_2$, $GaCl_3 \cdot RNO_2$, or SbF_5 catalyze the benzylation of benzene or toluene cleanly, giving moderate yields, without causing the excessive side reactions that occur with the uncomplexed Lewis acids [13]. Similarly, such adducts as $BF_3 \cdot OEt_2$ or $BF_3 \cdot C_6H_5OH$ act as mild Friedel – Crafts catalysts.

Impurities in the catalysts can alter both the yield and the course of the reaction catalyzed by Lewis acids. For example, the presence of ferric chloride in aluminum chloride can decrease product yield markedly, and hence the catalytic activity of Lewis acids depends on the method of their preparation.

Isomerization of the Alkylating Agents. Because of the acidic reaction conditions, the alkylating reagents often undergo rearrangements and are generally transformed into the most highly branched isomer possible. For instance, the reaction of benzene with propyl chloride leads mainly to isopropylbenzene, and that with *n*-butyl chloride to the formation of *sec*-butylbenzene. Under Friedel – Crafts conditions, isomerization of the alkylating agent is initiated by migration of a hydrogen atom and not by direct carbon rearrangements. The driving force is the formation of the most stable carbocation, following the usual trend: primary < secondary < tertiary. For example, the alkylation of benzene with long-chain linear 1-olefins leads not only to the 2-alkylbenzene but in most cases also to a random distribution of the phenyl substituent along the alkyl chain. This effect could result also from the isomerization of the alkylated reaction products, because *n*-butylbenzene is transformed into *sec*-butylbenzene in the presence of a Friedel – Crafts catalyst, such as $AlCl_3$ [51].

Depending on the reaction conditions, alkylation of benzene with tertiary alkyl halides often leads to the formation of secondary alkylbenzenes rather than to the tertiary alkylbenzenes. For example, alkylation of benzene with 2-chloro-2,3-dimethylbutane gives mainly 2,2-dimethyl-3-phenylbutane via isomerization of the primary product *tert*-hexylbenzene:

Table 2. Catalysts for the Friedel – Crafts alkylation of aromatic compounds

Group	Examples	Type of acid
Acidic halides	$AlCl_3$, $AlBr_3$, $SnCl_4$, $SbCl_5$, $FeCl_3$	Lewis acids
Metal alkyls and alkoxides	AlR_3, BR_3, ZnR_2, $Al(OPh)_3$	Lewis acids
Proton acids	HCl, HCl – $AlCl_3$, H_2SO_4, HF, H_3PO_4	Brønsted acid
Acidic oxides and derivatives	zeolites, mixed oxides and solid superacids, clays, heteropolyacids	Brønsted/Lewis acid
Supported acids	$H_3PO_4 - SiO_2$, $BF_3 - Al_2O_3$	Brønsted/Lewis acid
Cation-exchange resins	Permutit Q, Amberlite IR 112, Dowex 50, Nafion – silica, Deloxan	Brønsted acid

The primary product, *tert*-hexylbenzene, can be isolated only if less active catalysts, such as ferric chloride, are chosen [52].

Reactivity of Aromatic Substrates. The Friedel – Crafts alkylation of aromatic compounds, as an electrophilic substitution, is influenced by substituents present on the aromatic substrate. For example, electron-donating substituents, such as alkyl, NR_2, or OR (R = alkyl), lead to enhanced reactivity, and the new substituent enters preferentially in the ortho or para position. Therefore the alkylation of benzene with olefins leads to the monosubstituted benzene, which in turn reacts faster with a further olefin molecule than benzene itself does, resulting in a complex product mixture of mono- and polyalkylated benzenes [53]:

$$C_6H_6 + \text{olefin} \xrightarrow{k_1} C_6H_5R$$

$$C_6H_5R + \text{olefin} \xrightarrow{k_2} C_6H_4R_2$$

$$C_6H_4R_2 + \text{olefin} \xrightarrow{k_3} C_6H_3R_3$$

R = isoalkyl; $k_1 < k_2 < k_3$

The degree of polysubstitution, however, is influenced by reaction conditions and is lowered by steric hindrance by bulky alkyl groups, as shown in Table 3.

Benzene can be monoalkylated in good yields by bulky olefins, such as cyclohexene or linear $C_6 - C_{18}$ olefins [54]. In the case of ethylene or propene monoalkylation is made possible by recycling the polyalkylated products and by choosing suitable reaction conditions, as in the industrial synthesis of ethylbenzene and cumene. In the alkylation of monosubstituted benzenes, initially the ortho and para isomers predominate, as Table 4 shows. However, in most cases subsequent isomerization leads to an equilibrium mixture rich in the meta product. Only if the ortho position is sterically hindered is para substitution favored. For example, the reaction of benzene and 4-methylcyclohexene, catalyzed by HF, gives 75 % monoalkyl derivative and 25 % dialkyl derivative, of which 75 % is the para isomer and only 25 % the meta isomer [55]. Similarly, alkylation of cumene by 2-butene over $BF_3 - H_3PO_4$ yields 91 % para product [56], and the dialkylation of benzene with propene over silica – alumina gives preferentially *p*-diisopropylbenzene, which can be used for the synthesis of terephthalic acid and hydroquinone [57]. Substitution of benzene by halides leads to deactivation, as is evident from Table 5.

Table 4. Initial distributions (mass fraction in %) in the alkylation of toluene [53]

Alkylating agent	% Product distribution		
	o	*m*	*p*
C_2H_4	48	30	22
C_3H_6	42	21.5	36.5

Phenols or phenyl ethers react much faster than benzene in alkylation because of the considerably enhanced electron density in the ortho and para positions.

Table 5. $AlCl_3$-catalyzed alkylation with propene in CH_3NO_2 at 25°C [58]

Aromatic compound	k_{rel}	Isomer distribution, mass fraction in %		
		o	*m*	*p*
Benzene	1.00	–	–	–
Fluorobenzene	0.23	41.3	2.1	56.4
Chlorobenzene	0.11	53.9	5.1	41.0
Bromobenzene	0.07	55.4	8.6	36.0

Reactivities as well as product and isomer selectivities in microporous materials largely depend on the type, the number and the strength

Table 3. Relative rate constants for polysubstitution [53]

Reactants	Catalyst	Temp., °C	k_1	k_2	k_3	k_4	k_5	k_6
$C_6H_6 + C_2H_4$	$AlCl_3$	70	1	0.52	0.23	0.08	0.12	0.15
$C_6H_6 + C_3H_6$	$AlCl_3$	70	1	0.85	0.28	0.02	–	–
$C_6H_6 + C_3H_6$	HF	70	1	2.24	0.06	–	–	–
$C_6H_5CH_3 + C_3H_6$	$BF_3 - H_3PO_4$	50	1	0.22	0.06	–	–	–

of the acid sites as well as on the geometry of the zeolite pores (see page 6). Generally, higher temperatures are required for the alkylation process using solid catalysts, exceptions from this rule being only observed with very strong solid acids, i.e., solid superacids. An excellent review on mechanisms and product distributions of organic reactions on zeolites is given in [46].

Dealkylation and Transalkylation. Many of the catalysts used to alkylate aromatic compounds can be used, especially at higher temperatures, to reverse the alkylation reaction [59]. For example, alkylbenzene heated with $AlCl_3$ form mixtures of benzene and polyalkylated benzenes:

$$C_6H_5R \underset{}{\overset{AlCl_3}{\rightleftharpoons}} C_6H_6 + C_6H_5R + C_6H_4R_2 + C_6H_3R_3 + \ldots$$

The tendency of alkylaromatic compounds to disproportionate depends also on the structure of the alkyl substituent. The following order is observed [60]:

$$\textit{tert}\text{-}C_4H_9 > \textit{iso}\text{-}C_3H_7 > \textit{n}\text{-}C_3H_7 > C_2H_5 > CH_3$$

For example, disproportionation and transalkylation of methylbenzenes takes place at 300 – 450 °C in the presence of solid acid catalysts such as $SiO_2 - Al_2O_3$, whereas disproportionation and transalkylation of ethylbenzenes and isopropylbenzenes occur below 100 °C with typical Friedel – Crafts catalysts [53].

This intermolecular alkyl group transfer finds different applications in industrial processes. For example, in the synthesis of ethylbenzene, the undesired dialkylation product, which is formed in considerable amounts, reacts with an excess of fresh benzene:

$$C_6H_4(C_2H_5)_2 + C_6H_6 \rightleftharpoons 2\,C_6H_5(C_2H_5)$$

By this transalkylation process a high conversion of ethylene to ethylbenzene is achieved [61]. The reverse reaction, the disproportionation of monoalkylbenzenes, leads almost exclusively to the meta isomer in the presence of an excess of $BF_3 - HF$ [62]:

$$2\,C_6H_5(C_2H_5) \rightleftharpoons C_6H_6 + C_6H_4(C_2H_5)_2 \text{ (99 \% meta)}$$

This is attributed to the high stability of the complex $[m\text{-}Et_2C_6H_5]^+[BF_4]^-$. A similar type of complex is used commercially by Japan Gas to extract *m*-xylene selectively with $HF - BF_3$ from mixtures of C_8 aromatic compounds [63].

The alkylation – dealkylation equilibria mentioned above also explain product distribution in the alkylation of substituted aromatic compounds. The ortho and para isomers formed initially, which can be isolated after short reaction times (kinetic control), isomerize with prolonged reaction times to the more stable meta isomers (thermodynamic control).

Dealkylation is used commercially to convert toluene to benzene, to isomerize *m*-xylene to the desired ortho and para derivatives, and to disproportionate toluene to benzene and xylenes.

2.1.1. Alkylation of Benzene

There are three major commercial uses of the alkylation of benzene:

1) Alkylation with ethylene to ethylbenzene as an intermediate for styrene production. The production capacity for ethylbenzene was ca. 20×10^6 t/a in 1991, where the USA, Western Europe, and Japan held 5.3, 4.8, and 3.3×10^6 t/a, respectively. More than 95 % of the ethylbenzene produced worldwide is converted to styrene, minor amounts are used as solvents.
2) Alkylation with propene to cumene as an intermediate for phenol production, with acetone as the byproduct. The production capacity for cumene was ca. 7.5×10^6 t/a in

1992, where the USA, Western Europe and Japan held 2, 1.7 and 0.7×10^6 t/a, respectively. The largest fraction of the world's cumene production is converted to phenol in the Hock process, minor quantities are used admixed with other alkylbenzenes as octane enhancers.

3) Alkylation with long-chain olefins (with 10 – 18 carbon atoms) to alkylbenzenes, which are sulfonated to give surface-active compounds. The production capacity for linear alkylbenzenesulfonates (LAB) in 1992 in the USA, Western Europe, and Japan was 180 000, 485 000 and 197 000 t/a, respectively.

Alkylation of benzene with ethylene gives ethylbenzene [*100-41-4*] in a fast, exothermic reaction:

($\Delta H = -113$ kJ/mol)

Considerable amounts of polyethylbenzenes are formed as side products in this process, which can be carried out in the liquid phase or in the vapor phase. *1,4-Diethylbenzene* [*105-05-5*] (→ Hydrocarbons) is of commercial interest because its dehydrogenation product, 1,4-divinylbenzene [*1321-74-0*], is a crosslinking agent for polyolefins and is used widely in the production of ion-exchange resins.

In the *liquid-phase processes,* $AlCl_3$ is the most widely used catalyst, but other catalysts, such as BF_3, $FeCl_3$, $ZrCl_4$, $SnCl_4$, H_3PO_4, or alkaline-earth phosphates, also are used commonly [63]. The reaction is carried out at atmospheric pressure at 85 – 95 °C [64], [65]. For process details, see → Ethylbenzene.

The *vapor-phase* ethylation of benzene is common practice, especially in the United States, and typically is carried out at about 300 °C and 40 – 65 bar over acidic heterogeneous catalysts such as $Al_2O_3 \cdot SiO_2$ (Koppers Co.) or $H_3PO_4 - SiO_2$ (Universal Oil Products). The selectivity to monoalkylation is improved by use of a low ethylene-benzene (0.2 : 1.0) ratio [65], [66].

Universal Oil Products developed the Alkar process, used commercially in several plants since 1966. The catalyst is the noncorrosive boron trifluoride supported on a modified anhydrous alumina, which is also active for de- and transalkylation [67]. An unusually wide range of ethylene concentration (5 – 95 %) in the feed gas can be used, such as that in the off-gas from catalytic cracking, or that from a demethanizer overhead; alternatively, high-purity ethylene can be used. For example, the Alkar process can be adapted readily for use in the refinery. Preferred process conditions are temperatures of about 300 °C and pressures of about 60 bar, leading to quantitative conversion of ethylene [68]. For further details, see → Ethylbenzene.

The isomer distribution (mass fraction in %) obtained by alkylation of benzene with ethylene using the Alkar catalyst is as follows:

Diethylbenzenes:
1,2- (26);
1,3- (49); and
1,4- (25)
Triethylbenzenes:
1,2,3- (3);
1,2,4- (35); and
1,3,5- (62)

A variety of other metal halide Friedel – Crafts-type catalysts and mineral acids have been used on the laboratory scale for benzene ethylation [69], [70]. Of special interest are zeolite catalysts, which have been studied widely for this reaction [71], [72]. A commercial fixed-bed vapor phase process utilizing Mobil's proprietary ZSM-5 zeolites was introduced by Mobil Oil and Badger [73]. The reaction is carried out at 420 – 430 °C and 15 – 20 bar. Pure or diluted ethylene can be used as the feedstock after purification from sulfur, water, and propene. Polyalkylbenzenes can be recycled for transalkylation, resulting in a final yield of ethylbenzene of 98 – 99 mol %. The catalyst is regenerated periodically using oxygen-containing gas streams.

More recently, Raytheon Eng.& Constr. Inc. licensed Mobil/Badger's EBMax Process using Mobil's proprietary MCM-22 zeolite catalyst [74]. This process operates in liquid phase, contrary to Mobil/Badger's ZSM5-zeolite based gas-phase technology [46]. Another fixed-bed, liquid-phase alkylation technology is licensed by Lummus/Unocal/UOP employing a unique

zeolite-based catalyst developed by Unocal. The catalyst is based on a Y-type zeolite [75].

The latest zeolite alkylation technology yields ethylbenzene of 99.5 – 99.9 % purity. Catalyst lifetime is indicated to range between 1 and 3 years. Catalyst regeneration is easily achieved by thermal treatment in oxygen containing gas streams.

Zeolite catalysts offer the advantage of being noncorrosive and environmentally benign compared to liquid Brønsted or Lewis acid catalysts. This renders construction requirements, handling, and disposal much easier, thus, yielding economic benefits.

Amorphous aluminum silicates similar to those utilized in catalytic cracking also have been studied [76]. Although these catalysts give low conversions per pass, they are regenerated easily. Also, polyethylbenzene production is moderate and recycling by transalkylation is possible [76].

Alkylation of benzene with propene leads in an exothermic reaction to cumene [*98-82-8*]:

($\Delta H = -113$ kJ/mol)

The first cumene processes were developed between 1939 and 1945 to meet the demand for high-octane aviation gasoline. Today, almost all of the cumene produced as a pure compound is used for the synthesis of phenol (→ Phenol); acetone is also recovered from the process. The remainder is utilized for the production of α-methylstyrene [65], [77].

Both liquid- and vapor-phase processes are used for the commercial synthesis of cumene. The most widely used is the *liquid-phase process* of Universal Oil Products, which operates with a solid phosphoric acid catalyst (SPA, H_3PO_4 supported on diatomaceous earth). The conversion is carried out at 15 – 35 bar and temperatures of 200 – 250 °C. A 5 : 1 molar ratio of benzene to propene is necessary to prevent polyalkylation and to achieve a high conversion (ca. 94 %) of propene. The conversion is lowered to 70 % if a 4 : 1 benzene – propene feed is used. Increase of pressure and temperature enhances conversion rather than yields of cumene [78].

Beside the SPA catalyst, sulfuric acid and $AlCl_3$ are used for the production of cumene. For further information, see [79] and → Hydrocarbons., Chap. 3.7.

Novel, zeolite-based cumene production technologies were developed by Mobil/Raytheon, UOP, CDTech, Dow/Kellogg and Enichem [80–83]. Mobil is using its own MCM-22 zeolite, UOP utilizes a proprietary zeolite in its QMax process. Dow is using a highly dealuminated mordenite zeolite and Enichem employs a BEA-zeolite catalyst [75].

Common to most of the novel processes are two reactors and a distillation unit. In the first reactor the alkylation takes places, while in the second reactor heavy ends (tri- and polyisopropylbenzenes) are transalkylated with fresh benzene. CDTech is using a slightly different reactor concept, i.e., a reactive distillation (→ Reactive Distillation) unit employing a Y-type zeolite. For references see also [84–86]. Mobil's technology is easy to retrofit to existing plants and by mid-1998 six revamps with a total capacity of about 3×10^6 t/a were in operation [81].

Alkylation of cumene with propene, over a pretreated aluminum silicate catalyst and in the liquid phase under pressure at 150 – 250 °C, leads to a mixture of mainly *p*-diisopropylbenzene [*100-18-5*] and *m*-diisopropylbenzene [*99-62-7*] with only traces of the ortho isomer.

p-Diisopropylbenzene (*bp* 210.4 °C at 101.3 kPa) can be separated by distillation from the mixture of *m*-diisopropylbenzene (*bp* 203.2 °C) and *o*-diisopropylbenzene (*bp* 203.8 °C), which is isomerized in a second reactor at 240 – 320 °C over the same aluminum silicate catalyst. In this second reactor, polyalkylbenzenes are transalkylated with benzene to give further *p*-diisopropylbenzene [87]. *m*-Diisopropylbenzene can be produced in a similar manner, with only slight modifications. The diisopropylbenzenes are also important intermediates for the production of hydroquinone (or resorcinol) (→ Hydroquinone).

Alkylation of Benzene with Higher Olefins. Monoalkylbenzenes with 10 – 14 carbon atoms in the alkyl chain, such as dodecylbenzene [*123-01-3*], are important intermediates

for alkylbenzenesulfonates, which are widely used in anionic commercial detergent products (→ Surfactants).

Until about 1965, the most important olefin for this reaction was propene tetramer. However, the resistance of detergents based on propene tetramer to biodegradation led to environmental problems and hence to the introduction of linear alkylbenzenesulfonates. The feedstock for the production of alkylbenzenesulfonates therefore consists of linear olefins with 10 – 14 carbon atoms. The catalysts generally used for this reaction are liquid HF, H_2SO_4, or $AlCl_3$ and the following conditions are suitable [50]:

1) HF: 0 – 10 °C, 4 – 10 mol of benzene to 1 mol alkene, 2 – 3 kg of alkene per kilogram of HF
2) H_2SO_4: 10 – 30 °C, 4 – 5 mol of benzene to 1 mol alkene, 2 volumes of alkene per volume of 96 – 98 % H_2SO_4
3) $AlCl_3$: 55 – 60 °C, 3 – 4 mol of benzene to 1 mol olefin, 25 mol of alkene per mole of $AlCl_3$

The HF process is reported to be the most economical with respect to catalyst consumption. The process is carried out in the liquid phase at atmospheric pressure and 10 °C. Effective stirring and cooling is necessary to remove the heat of the exothermic reaction. This determines the reaction times. The acid strength is maintained at 79 % HF, and a high benzene to olefin ratio is needed to insure complete conversion of olefins and a high selectivity to monoalkylates. The products are separated from the acid in a settler, washed, and distilled at atmospheric pressure to recover benzene and at reduced pressure to isolate the alkylbenzenes [65], [88].

More recently, many solid alkylation catalysts for the production of linear alkyl benzenes have been described in the literature, however, since a slow-down in LAB demand has taken place in the industrialized regions, only UOP (Detal process) has commercialized a new technology using a noncorrosive catalyst to replace HF. UOP has patented a fluorided silica – alumina catalyst [89] which is operated in liquid phase at about 130 °C. The process achieves 92 % linearity (i.e., unbranched alkyl chain, see Table 6) at 100 % conversion and a selectivity of 90 %.

The detergent properties of the alkylbenzenesulfonates are not only influenced by the degree of branching of the alkyl side chain – three to five methyl groups in dodecylbenzene are optimum, whereas the highly branched butene oligomers were not suitable as starting material [64] – but depend also on the position of the phenyl group on the alkyl chain [90]. Irrespective of the position of the olefin double bond, Friedel – Crafts alkylation leads to an equilibrium product mixture with a random distribution of the phenyl over the alkyl chain. The product composition, however, is affected by the nature of the catalyst, as shown in Table 6, where the product distributions obtained from the reaction of benzene with 1-dodecene [*112-41-4*] utilizing $AlCl_3$, HF, and H_2SO_4 as catalyst are listed [54].

Table 6. Isomer distribution of dodecylbenzenes obtained from 1-dodecene and benzene

Phenyldodecane, Mass fraction in %	Catalyst, temperature		
HF, 16 °C	$AlCl_3$, 30 °C	H_2SO_4, 0 °C	
1-	0	0	0
2-	20	32	41
3-	17	22	20
4-	16	16	13
5-	23	15	13
6-	24	15	13

As expected, no terminal phenyldodecanes are observed. With $AlCl_3$ and H_2SO_4 as the catalyst, the 2-phenyl isomer is formed preferentially, and the 3- to 6-phenyl isomers occur in lesser amounts. In contrast, with HF, the 3- to 6-phenyl isomer formation is enhanced. This can be explained by the ability of Lewis acids, such as $AlCl_3$, to isomerize the phenylalkanes formed, whereas the proton acids isomerize only the olefins prior to the final alkylation of the benzene.

Alkylation of benzene with alkyl chlorides also is used commercially for the production of detergent alkylates. The alkyl chloride obtained from the chlorination of paraffins contains about 70 % paraffin. This mixture then reacts with a large excess of benzene in an enameled alkylating tower at 80 °C using $AlCl_3$ as the catalyst. The hydrogen chloride, which is formed in stoichiometric amounts, insures thorough mixing of the reactants and is separated at the top of the reactor. The products are separated from the catalyst in a settler, neutralized, washed, and distilled to recover benzene and paraffin, which are recy-

cled; they are then distilled under reduced pressure to isolate the alkylates [91] (→ Surfactants).

Considerable amounts of indane and tetralin derivatives are formed as byproducts because of the dichloroalkane impurities in the alkyl chloride:

Alkylbenzenes with more than 15 carbon atoms in the side chain lead to alkylbenzenesulfonates that are almost insoluble in water but are extremely soluble in organic media, such as mineral oils. Such solutions in mineral oil are used in the metal-working industry as drilling and cutting fluids or in the textile industry as spinning or batch fluids. Alkylbenzenesulfonates of this type are being used increasingly as flooding agents in the enhanced recovery of petroleum.

Miscellaneous Alkylations of Benzene. Benzene can be alkylated by a variety of other linear, branched, cyclic, aryl- or otherwise substituted olefins, alkyl halides, alcohols, ethers, and compounds such as alkynes and dienes. For a comprehensive review of these reactions, see [92]. Some of these reactions have been commercialized, such as the synthesis from benzene and isobutene of *tert*-butylbenzene [*98-06-6*], which is used for the production of perfumes.

2.1.2. Cycloalkylation

A typical example of *intermolecular* cycloalkylations is the formation of 9,10-dihydroanthracene [*613-31-0*] (together with some diphenylmethane) from dichloromethane and benzene:

Anthracene derivatives also are formed in this reaction [93].

Intramolecular cycloalkylation is possible for alkylated aromatic compounds carrying a double bond or a functional group, such as a halogen or hydroxy group, in the side chain. For example, 3-phenyl-1-propene [*300-57-2*] is isomerized to give indane [*496-11-7*] in the presence of $AlCl_3$ [94]:

A synthesis for anthraquinone [*84-65-1*], based on cycloalkylation, was developed by BASF:

Styrene is dimerized in the liquid phase to 1-methyl-3-phenylindane, utilizing phosphoric acid as catalyst, followed by catalytic vapor-phase oxidation to anthraquinone [95], [96].

Arylation of aromatic compounds can be achieved by reaction with aryl halides, by reaction with diazonium halides, and by dehydrogenating condensation.

Because of their low reactivity, aryl halides can be used only under specific conditions as Friedel–Crafts arylating agents. Their reactivity is F ≫ Cl > Br. Aromatic hydrocarbons can be arylated with fluorobenzene to give the corresponding biphenyls [97]. The decomposition

of aryldiazonium tetrafluoroborates in aromatic solvents gives ring-arylated products as well as fluorobenzene [98].

The Scholl reaction is the dehydrogenating condensation of an aromatic compound in the presence of Friedel–Crafts catalysts. Typical examples are the formation of perylene [*198-55-0*] from naphthalene

and the formation of 2,2′-dipyridyl [*366-18-7*] from pyridine

High molecular weight polycondensated aromatic compounds also can be formed [92].

2.1.3. Alkylation of Substituted Benzenes

As pointed out in Section 2.1.1, the alkylation of benzene rarely leads to the monoalkylated product only, but to a complex mixture with di- and polysubstituted compounds. The reactivity as well as the orientation in the second substitution step depends on the electronic and steric properties of the first substituent and on the bulkiness of the alkylating agent.

Some dialkylated benzenes are of considerable commercial importance [65], [73]. For example, diethylbenzenes are useful for improving the octane ratings of motor fuels and are obtained as side products in ethylbenzene production processes. Dialkylbenzenes can be dehydrogenated to give divinylbenzenes that are used for cross-linking

of polyolefins, such as polystyrene in the production of ion-exchange resins. Similarly, ethylmethylbenzene, obtained by ethylation of toluene, is of industrial interest as a starting material for styrenes that are methyl substituted in the aromatic ring. Another example is the production of diisopropylbenzene by reaction of propene with cumene (see page 12).

The alkylation of toluene with propene to give cymene [*25155-15-1*] is carried out commercially, for example, by Sumitomo Chemicals [99]:

The cymene formed is rich in the meta and para isomers and is oxidized to give acetone and cresols, which consist of ≧99.5 % *m,p*-cresols and ≧60 % *m*-cresol and are used as raw materials for phenolic resins or for plasticizers.

Polymethylated benzenes obtained by disproportionation, for example, of toluene (see Section 2.1.5), or methylation of benzene or toluene [100] can be oxidized to the corresponding acids, which are used in such polymers as polyesters, polyamides, and polyimides.

A vast amount of literature on preparative alkylations of substituted benzenes exists, and this field has been comprehensively reviewed [101]. Some of these reactions are applied for the production of fine chemicals, such as dyes and pharmaceuticals.

Alkylation of higher aromatic compounds, such as biphenyl, indane, and tetralin, or of polynuclear aromatic compounds, such as naphthalene, acenaphthene, anthracene, fluorene, and phenanthrene, also has been reported [101].

The *alkylation of naphthalene* [*91-20-3*] with higher olefins has found commercial application for the production of fluorescent agents used in lubricating oils. The reaction is carried out in the liquid phase using $AlCl_3$ as the catalyst at temperatures up to 180 °C [102]. Another application of naphthalene alkylation is the production of detergents of the "Nekal" type (BASF), which are alkylnaphthalenesulfonates. These compounds were among the first synthetic detergents and are still used in the textile industry as surfactants:

They are prepared in a "one-pot" process by reaction of naphthalene with butanol or hexanol or mixtures of propanol – butanol in the presence of 96 % sulfuric acid at 50 °C. After the alkylation is complete, 25 % oleum is added for sulfonation. The oxidation of 2-isopropylnaphthalene, according to the Hock process, leads to 2-naphthol [*135-19-3*]. 2-Isopropylnaphthalene can be obtained together with small amounts of the 1-isopropyl isomer by reaction of naphthalene with propene using $ZnCl_2$ or aluminum silicates as the catalyst at 150 – 200 °C [103].

2,6-Dialkylnaphthalenes have attracted much interest. They are oxidized to 2,6-naphthalenedicarboxylic acid which is used for the production of the high-performance plastic poly(ethylene-2,6-naphthalene dicarboxylate) (polyethylenenaphthenate, PEN). Various shape-selective catalysts have been described to alkylate naphthalenes, among which mordenite seems to be the most effective [104]. However, another route to 2,6-dimethylnaphthalene was commercialized by Amoco in 1995 at a capacity of about 40 000 t/a. Amoco alkylates *o*-xylene with butadiene over a strongly basic catalyst yielding *o*-tolylpentene, which further undergoes cyclization, dehydrogenation, and isomerization [105].

2.1.4. Alkylation of Phenols

The alkylation of phenols is a very important reaction industrially, and the alkylphenols are used widely in a variety of applications, such as antioxidants, herbicides, insecticides, or polymers. The nucleophilicity of the hydroxyl group is associated with increased electron density in the aromatic ring, which facilitates electrophilic substitution. Therefore alkylation occurs under conditions milder than those needed with aromatic hydrocarbons [101].

Depending on the reaction conditions, catalysts and alkylating agents, predominantly *ortho*- or *para*-monoalkylated, 2,4- or 2,6-dialkylated, and 2,4,6-trialkylated phenols are formed.

Thermodynamically more stable *meta* isomers are formed at higher temperatures by secondary reactions. At low temperatures and low catalyst concentrations, alkyl aryl ethers also are found in significant amounts, whereas at higher temperatures, catalyst concentration, and acid strength, the alkylphenols are formed predominantly [106]. Olefins, alcohols, and alkyl halides are the alkylating agents. For industrial phenol alkylation, three main types of processes have been developed:

1) *Liquid-phase alkylation,* in which the alkylating agent is added to a solution or suspension of the catalyst in the phenol. The catalyst must be separated after the reaction, and the last traces of the catalyst decomposed by neutralization.
2) *Fixed-bed liquid-phase processes,* in which the reactants pass over the catalyst at elevated pressures in tubular reactors, which are cooled externally.
3) *Vapor-phase alkylation,* in which the phenol and the alkylating agent, such as methanol or an olefin, are sent to a fixed-bed reactor operating at 300 – 400 °C. The heat of reaction must be removed efficiently.

The product is recovered in all cases by distillation. The unconverted phenols and alkylating agents are recycled and the various mono-, di-, and trialkylated phenols separated. In order to prevent side reactions, such as isomerization, transalkylation, and disproportionation, during distillation, it is essential to remove all traces of the acidic catalyst.

Catalysts. In the liquid-phase processes, Lewis acid catalysts, such as $AlCl_3$, BF_3, or $Al(C_6H_5O)_3$; proton acids, such as HF, H_2SO_4, H_3PO_4, or *p*-tolylsulfonic acid; or acidic ion-exchange resins, such as Nafion resins or sulfonated polystyrenes, are applied. Catalysts suitable for the vapor-phase processes must be of high thermal stability. Typical examples are montmorillonites ($Al_2O_3 \cdot 4\,SiO_2 \cdot H_2O$), zeolites, such as faujasite, and metal oxides, such as γ-Al_2O_3, MgO, CaO, and $Fe_2O_3 - CrO_3$ [107–109].

Alkylation with alcohols, especially methanol, usually is carried out over metal oxides, preferably MgO. For olefins, the acidic catalysts and γ-Al_2O_3 are used. The heterogeneous catalysts, such as ion-exchange resins or zeolites, gradually are replacing the liquid acids because of easier product separation and lower catalyst consumption [107–110].

Regioselectivity can be controlled using a variety of catalysts. If HF, BF_3, $Al_2O_3 \cdot SiO_2$, or acidic ion-exchange resins are used, the alkylation of phenols with olefins leads predominantly to the *p*-substituted product. In contrast, $Al(C_6H_5O)_3$, which is formed from phenol and metallic aluminum, especially in the presence of traces of mercury salts, leads almost exclusively to the 2-alkylated and 2,6-dialkylated products. The high selectivity for ortho alkylation is explained by a six-membered transition state involving aluminum phenolate and an olefin [111]. Other metal salts of phenol, including those of zinc, magnesium, and calcium, are active. This reaction is not restricted to phenol; 2-naphthol, 2-cresol, or 4-cresol also can be alkylated by ethylene, propene, the butenes, cyclohexene, or other olefins. The highest reactivity is observed for isobutene, the lowest for ethylene [112], [113].

High selectivity to monoalkylated *o*-phenols by reaction of olefins with phenols is achieved with γ-Al_2O_3 as the catalyst. The reaction is carried out at elevated temperatures of 200 – 350 °C in the liquid phase at pressures of 20 – 200 bar. This process is well suited to continuous fixed-bed operation.

Heating alkylphenols, especially in the presence of acidic catalysts, leads to dealkylation, transalkylation, and isomerization [114]. The tendency of the alkylphenols to undergo these reactions depends on the nature of the alkyl substituent and increases in the order primary < secondary < tertiary alkyl; methyl substituents are rather inert. Isomerization leads to an equilibrium where the thermodynamically more stable 3 or 3,5 isomers prevail, and dealkylation occurs more easily in the ortho or para position than in the meta position. The regioselectivity of transalkylations is influenced also by the nature of the catalyst, and, therefore, in the presence of aluminum phenolate the ortho products prevail:

If different alkyl substituents are to be introduced into a phenol, the most sensitive tertiary alkyl is added last.

In industry, alkylphenols often are produced in batch operations, which offer higher flexibility. However, for compounds produced in large amounts, such as cresols, 2,6-xylenol (→ Cresols and Xylenols), 2-*sec*-butylphenol, 4-*tert*-butylphenol, octylphenol, nonylphenol, dodecylphenol, thymol, or 2,6-di-*tert*-butyl-4-methylphenol (→ Phenol Derivatives), continuous processes have been introduced with capacities of up to 25 000 t/a each. A survey of commercially important alkylphenols and their end uses is given in Table 7 [115–117].

Alkylation of phenol with methanol at elevated temperatures over a catalyst yields 2-cresol [*95-48-7*] (60 – 70 % at 50 % phenol conversion and 300 °C) and 2,6-xylenol [*576-26-1*], together with some 4-cresols, 2,4-, and 2,3-xylenols, and a little 3-cresol.

The reaction can be carried out in the liquid phase or in the vapor phase. In the *vapor-phase processes,* the reactants are fed at atmospheric or slightly elevated pressure at 300 – 450 °C into a tubular reactor containing the fixed-bed catalyst [118]. A high selectivity to 2-cresol and 2,6-xylenol is observed with activated Al_2O_3 at 300 °C [119] and with MgO and CeO_2 at 540 and 450 °C, respectively [120]. Use of highly acidic aluminum oxide, aluminum silicates, zeolites, and aluminum phosphate, especially at higher temperatures, leads to transalkylation-isomerization and thus to increased formation of 3-cresol and 4-cresol. In *liquid-phase processes,* catalysts such as Al_2O_3, $Al(OMe)_3$, $Al(OC_6H_5)_3$, or $ZnCl_2$ – HCl are used at elevated pressures [121], [122]. In all cases, the xylenol : cresol ratio increases with the methanol : phenol ratio, with temperature, and with pressure.

2,3,6-Trimethyphenol [*2416-94-6*] is produced by a continuous liquid-phase process from 2,6-xylenol and methanol, using a fixed-bed Al_2O_3 catalyst at 280 – 380 °C in a tubular reactor [123].

Alkylation of Phenols with Olefins. 2-Ethylphenol [*90-00-6*] is formed from ethylene and phenol in the presence of 1 – 2 % $Al(C_6H_5O)_3$ at 320 – 340 °C and 200 bar,

Table 7. Production and end use of alkylphenols [115], [117]

Alkylating agent	Phenol	Alkylphenol	End use
Methanol	phenol	2-, 3-, and 4-cresol	insecticides, herbicides, antioxidants, disinfectants, resins, plasticizers
		2,6-xylenol	polyphenylene oxide resins
		3,5-xylenol	vitamin E
Methanol	3,6-xylenol	2,3,6-trimethylphenol	vitamin E
Ethylene	phenol	2-ethylphenol (2,6-diethylphenol)	photochemicals
Propene	phenol	2-isopropylphenol (2,6-diisopropylphenol)	resins, plasticizers, antioxidants, insecticides, perfumes
Propene	3-cresol	3-methyl-6-isopropylphenol (thymol)	perfumes, disinfectants
	2-cresol	2-methyl-6-isopropylphenol (carvacol)	disinfectants, perfumes
1-Butene	phenol	2-*sec*-butylphenol (2,6-di-*sec*-butylphenol)	insecticides, herbicides, acaricides, resins
Isobutene	phenol	2-*tert*-butylphenol (2,6-di-*tert*-butylphenol)	antioxidants, insecticides
		2,4,6-tri-*tert*-butylphenol	acaricides, perfumes, resins
		4-*tert*-butylphenol	alkylphenol resins
Isobutene	4-cresol	2,6-di-*tert*-butyl-4-methylphenol	antioxidant
2-Methylbutene	phenol	4-*tert*-amylphenol	resins, antioxidants
Diisobutene	phenol	4-*tert*-octylphenol	resins, detergents, antioxidants, emulsifiers, surfactants
Tripropene	phenol	4-isododecylphenol	
Tetrapropene	phenol	4-isododecylphenol	

whereas the alkylation of phenol with propene to 2-isopropylphenol [*88-69-7*] can be carried out at 280 – 300 °C using γ-Al_2O_3 as the catalyst [108], [124]. The propylation of cresols to give thymol [*89-83-8*] or carvacol [*499-75-2*] is achieved in continuous liquid-phase processes using γ-Al_2O_3, aluminum silicates, or zeolites [115]. Under similar conditions, 2-*sec*-butylphenol [*89-72-5*] can be produced from phenol and *n*-butenes [124].

Because of the high reactivity of isobutene, the production of 2-*tert*-butylphenol [*88-18-6*] and 2,6-di-*tert*-butylphenol [*128-39-2*] can be carried out at 100 °C at pressures up to 20 bar in the presence of $Al(C_6H_5O)_3$. 4-*tert*-Butylphenol [*98-54-4*] is prepared at atmospheric pressure at 80 – 140 °C in the presence of H_2SO_4, H_3PO_4, BF_3, or preferably acidic cation-exchange resins [125].

The production of the important antioxidant 2,6-di-*tert*-butyl-4-methylphenol [*128-37-0*] from 4-cresol and isobutene is carried out at 70 °C using H_2SO_4 as the catalyst [126]. The alkylation of phenol with 2-methylbutenes at 100 – 120 °C in the presence of BF_3 or H_3PO_4 yields 4-*tert*-amylphenol [*80-46-6*], in the presence of an excess of 2-methylbutenes also 2,4-di-*tert*-amylphenol [127].

A most important process commercially is the alkylation of phenol with linear or branched olefins containing 6 – 20 carbon atoms to give alkylphenols, which after ethoxylating and sulfating, are used widely as anionic detergents. Diisobutene, tripropene, and tetrapropene are preferred as alkylating agents, and the reaction is catalyzed under mild conditions (50 – 85 °C) by BF_3 in continuous-batch or tubular reactors. Acidic cation-exchange resins, such as macroreticular sulfonated polystyrene, also are excellent catalysts that overcome the problem of catalyst separation. To achieve better temperature control, the reaction may be carried out in two stages, using a catalyst of reduced acidity in the first stage. A process of this type is utilized by Chemische Werke Hüls (now Degussa-Hüls) in Germany to produce nonylphenol [107], [110], [115]. In the first stage of this fixed-bed process, the temperature increases from 80 to 120 °C and in the second stage from 110 to 130 °C. Activated aluminum silicates also are used as catalysts but require higher reaction temperatures and longer reaction times.

A great variety of alkylphenols, haloalkylphenols, and related compounds are produced industrially and are used as oxidation inhibitors, detergents, bactericides, fungicides, insecticides, and disinfectants. This field

has been reviewed extensively (→ Cresols and Xylenols; → Phenol Derivatives) [101], [107], [108], [128].

2.1.5. Alkylation of Aromatic Amines

Because of the basicity of aromatic amines, acidic catalysts are not very suitable for the alkylation of these substrates. For example, the reaction of ethylene with aniline in the presence of the Friedel – Crafts catalyst $AlCl_3$ leads mainly to unidentified resinous products with small amounts of 2-ethylaniline. However, *aluminum anilide,* $Al(C_6H_5NH)_3$, which is formed in situ with the evolution of hydrogen by heating aluminum powder in aniline, is an active catalyst for this reaction. At 300 – 340 °C and 200 bar, 2,6-diethylaniline [*579-66-8*] is formed after 2 – 3 h, whereas at shorter reaction times 2-ethylaniline [*578-54-1*] also is formed [129].

The catalytic activity of aluminum anilide is enhanced by addition of Friedel – Crafts catalysts, such as $AlCl_3$, $SnCl_4$, $TiCl_4$, $SiCl_4$, BF_3, or $ZnCl_2$. Mixtures of alkali metals and $AlCl_3$ in aniline are also active systems, whereas alkali metals alone lead selectively to N-alkylation. The reaction has been extended to a variety of substituted anilines, such as 2-, 3-, and 4-toluidine, 2,6-, 2,4-, and 2,5-xylidine, 2-propylaniline, 2- and 3-chloroaniline, and α-naphthylamine. Diamines, such as *m*-phenylenediamine or 2,4-toluylenediamine, as well as secondary amines, such as diphenylamine, also can be alkylated.

The reactivity of the olefins decreases in the order ethylene > propene > 1-butene > isobutene, which is the reverse of the order observed in phenol alkylation with $Al(OC_6H_5)_3$ as the catalyst. However, in the case of isobutene, Friedel – Crafts catalysts, such as $AlCl_3$, BF_3, or montmorillonite, are active even at 200 – 250 °C, whereas with aluminum anilide only slow reaction occurs. With montmorillonite, 4-*tert*-butylaniline [*769-92-6*] is formed selectively, whereas with BF_3 or $AlCl_3$, mixtures of the 2 and 4 isomers are produced [129], [130].

The alkylation of anilines with methanol is catalyzed by molecular sieves. A complex mixture of 2-toluidine, 2,6- and 2,4-xylidine, and 2,4,6-trimethylaniline is formed. 2,6-Dialkylanilines, for example, 2-ethyl-6-methylaniline [*24549-06-2*], are produced industrially as intermediates for herbicides and dyes [115].

2.1.6. Alkylation of Heteroaromatic Compounds and Related Substrates

A variety of heterocyclic aromatic compounds, such as furanes, thiophenes, and *N*-heterocycles, can be alkylated, although little is known about commercial application of these reactions. Cyclopentadienyl derivatives undergo Friedel – Crafts alkylation in a similar manner.

Furan appears to be much more reactive in Friedel – Crafts alkylations than benzene. However, resinification of furans in the presence of acids occurs quite rapidly, which often makes product separation difficult. Using phosphoric acid on kieselguhr, furan can be alkylated with isobutene in 3 h at 100 °C to give 85 % yield of the alkylates together with small amounts of isooctene:

Whereas substitution in the 2 position is favored under mild conditions (50 °C, 1 h), the formation of products substituted in the 3 position is enhanced at longer reaction times (7 h), higher temperatures (150 °C), and greater catalyst concentrations. The formation of 2,5-di-*tert*-butylfuran [*4789-40-6*] also was observed [57], [101], [131].

Thiophene appears to be substantially more reactive in Friedel – Crafts reactions than aromatic hydrocarbons and can be alkylated with olefins, such as propene, 1-butene, 2-methylbutenes, or cyclohexene, and with alcohols, such as isopropyl alcohol and *tert*-butyl alcohol. Acidic catalysts, such as phosphoric acid at 60 °C or alumina silica at 200 °C, were used successfully, whereas H_2SO_4, HF, $BF_3 \cdot OMe_2$,

and $AlCl_3$ led to side reactions. In all cases, the thiophene substituted in the 2 position was observed, as well as higher-boiling material, such as dialkylated products [57], [132]. The removal of thiophene from cracked gasoline by refining with cold concentrated sulfuric acid is probably an alkylation reaction. The olefins present in the gasoline act as alkylating agents to give high-boiling alkylthiophenes, which remain as residue upon distillation [133].

***N*-Heterocycles** can be alkylated in the presence of aluminum amides. Because heterocyclic compounds, such as carbazole and indole, react only slowly with aluminum metal to give the amide, aluminum anilide is used as the catalyst. For example, carbazole reacts with ethylene in the presence of aniline and aluminum powder to give 1-ethylcarbazole [*19275-57-1*]. The reaction takes place in an autoclave at 280 °C and 200 bar.

Propene reacts under similar conditions to give 1-isopropylcarbazole [*1484-09-9*], but with a lower yield [130].

Alkylations using acidic catalysts also have been reported. For example, the formation of diisopropylcarbazole from carbazole and propene was observed at 90 – 100 °C in the presence of $AlCl_3$ [134]. The same reaction over an aluminum silicate gave tetra- and pentaisopropylcarbazole at 180 – 200 °C [135], and the ethylation of pyrrole was achieved at 200 – 370 °C over an aluminum silicate [101], [136].

Nonbenzenoid aromatic compounds, such as ferrocenes, fulvenes, azulenes, pseudoazulenes, indolizines, and cyclazines, resemble chemically not only the benzenoid systems but also the olefins. Compared to benzene derivatives, their electrophilic substitution reactions occur under milder conditions. Because these systems are often of low stability, both catalysts and reaction conditions have to be selected carefully.

Ferrocene [*102-54-5*] can be alkylated, in the presence of Lewis acids, such as $AlCl_3$, with a variety of substrates, such as methanol, ethyl, isopropyl, butyl, and benzyl halides, 1,2-dichloroethane, ethylene, propene, and isobutene. The reaction often yields complicated mixtures of homoannular and heteroannular (i.e., both rings are alkylated) products, because of the increased reactivity of the system after the first alkylation step [137], [138]. Alkylation of ferrocene with olefins seems more favorable; that with isobutene to give *tert*-butylferrocene occurs even at room temperature. At 100 – 150 °C, heteroannular tri-*tert*-butylferrocene is obtained in 44 % yield, together with some tetra-*tert*-butylferrocene. Steric hindrance prevents the attachment of more than two *tert*-butyl substituents to the same cyclopentadienyl ring [139]. A more detailed description of ferrocene alkylation and of alkylation reactions of other nonbenzenoid aromatic compounds can be found in [140], [141].

2.1.7. Miscellaneous Alkylation Reactions

The alkylation of aromatic compounds with bi- or polyfunctional reagents leads to a variety of useful mono-, di-, or polynuclear products of commercial interest.

Haloalkylations with bi- or polyfunctional alkylating agents to yield only primary haloalkylation products can be carried out under suitable reaction conditions. Cycloalkylation or linkage of two or more nuclei as shown in the second reaction can be avoided.

Typical haloalkylating agents are aldehyde – hydrogen halide, haloalkyl ethers, haloalcohols, and similar compounds [92]. Halomethylation, haloethylation, higher haloalkylation, as well as bis- and polyalkylation can be achieved. Zinc chloride is the

catalyst most often used; other catalysts include acidic halides ($ZnCl_2 - AlCl_3$, $SnCl_4$, $AlCl_3$ – ketones, $AlCl_3$ – pyridine) or proton acids (HCl, H_2SO_4, H_3PO_4, *p*-toluenesulfonic acid) [142].

A typical example of this reaction is the chloromethylation with formaldehyde – HCl (Blanc reaction) [143]:

Because this reaction leads to reactive intermediates, it is of considerable synthetic value. However, great care must be exercised because the intermediate chloromethyl ethers are extremely carcinogenic.

Hydroxyalkylation of aromatic compounds with aldehydes and ketones in the presence of acids is industrially very important. The electrophiles attacking the aromatic nucleus are formed from the aldehyde-ketone by reaction with a Lewis or proton acid (R, R′ = H, alkyl, aryl):

Further reaction proceeds according to the mechanism outlined in Section 1.3.1 and leads to a substituted benzyl alcohol; this, under acidic conditions, reacts with a further molecule of the aromatic compound to yield a substituted diarylmethane. This process is exemplified by the reaction of acetone with phenol, giving 2,2-bis-(4-hydroxyphenyl)propane (bisphenol A) (→ Phenol Derivatives):

This compound is produced industrially in continuous processes using H_2SO_4 (or, in the Hooker process, dry HCl) as the catalyst and methyl mercaptan as promoter. Almost quantitative yields are obtained at 50 °C [63]. Also, cation-exchange resins are being used increasingly as catalysts, because of the simplified catalyst separation [107]. Bisphenol A is utilized mainly for the production of epoxy- and polycarbonate resins.

Hydroxyalkylations (Table 8) are extremely versatile; numerous alkyl- and aryl-substituted aldehydes and ketones react with a variety of aromatic compounds [144]. For instance, 1,1,1-trichloro-2-bis-(4-chlorophenyl)ethane (DDT) [*50-29-3*], once a widely used insecticide, is formed from chloral and chlorobenzene. The reaction of phenol with formaldehyde leads to hydroxymethylphenols, which condense at elevated temperatures to phenol resins.

If an oxirane is used as the alkylating agent, a β-hydroxyalkyl aromatic compound is obtained. For example, the reaction of ethylene oxide [*75-21-8*] with benzene in the presence of a stoichiometric amount of $AlCl_3$ leads to an aluminum alkoxide, which gives β-phenylethanol [*60-12-8*] on hydrolysis [145].

Amidomethylation is possible using the *Tscherniac-Einhorn reaction,* where *N*-hydroxymethylamides or the corresponding imides react with an aromatic compound under mild conditions in sulfuric acid [146].

Less reactive aromatic compounds, such as benzoic acids, also can be amidoalkylated; even

Table 8. Alkylation of aromatic compounds by aldehydes and ketones [115]

Alkylating agent	Aromatic compound	Product	End use
H_2CO	C_6H_5OH	$2-HO-C_6H_4-CH_2OH$	salicylaldehyde, salicyl alcohol
H_2CO	$(C_6H_5O)_3B$	$(2-HOCH_2-C_6H_4-O)_3B$	2-cresol
H_2CO	$C_6H_5NH_2$	$(4-H_2N-C_6H_4-)_2CH_2$	methylenediphenyl diisocyanate, resins, adhesives
H_2CO	$2-Cl-C_6H_4NH_2$	$(3-Cl-4-NH_2-C_6H_3)_2CH_2$	polyurethanes
CH_3CHO	$C_6H_5CH_3$	$(4-CH_3-C_6H_4-)_2CHCH_3$	heat-exchanger liquid
CCl_3CHO	C_6H_5OH	$(4-HO-C_6H_4-)_2CHCCl_3$	polymers
HO_2CCHO	C_6H_5OH	$4-HO-C_6H_4-CH(OH)-CO_2H$	4-hydroxybenzaldehyde, 4-hydroxyphenylacetic acid

nitro substituted aromatic compounds can be alkylated using *N*-chloromethylcarboxylic acid amides in the presence of $AlCl_3$ [146].

2.2. Acylation

In Friedel – Crafts acylation, an aromatic ketone is formed by reaction of an aromatic compound with an acylating agent, such as an acyl halide, an acid anhydride, an acid, or an ester, in the presence of an acidic catalyst:

$$C_6H_6 + RCOX \xrightarrow{cat.} C_6H_5COR + HX \quad R = \text{alkyl, aryl}$$

The acylation of aromatic substrates is of considerable industrial interest for making aromatic intermediates used for the production of pharmaceuticals, insecticides, plasticizers, dyes, perfumes, and other commercial products. These speciality products usually are produced on a much smaller scale than alkylation products. Some examples of industrial interest are given in Table 9.

Acylation is extremely versatile, leading to a variety of products that include aromatic aldehydes, alkyl aryl ketones, symmetric and unsymmetric diaryl ketones, and cyclization products [147–149]. Generally, acylating agents react more readily than alkylating agents, and therefore acylations can be carried out usually under quite mild conditions. Electron-donating substituents in the aromatic substrate, such as alkyl, hydroxyl, or alkoxy groups, lead to enhanced reactivity.

On the other hand, aromatic compounds containing electron-withdrawing substituents, such as the nitro, acyl, carboxyl, or nitrile groups, are attacked only with great difficulty, even by the most active acylating agents. The introduction of the first acyl group hinders the entry of a second, and disubstitution in the same ring is therefore rare [147]. Examples for the disubstitution are the diacylation of mesitylene [150] or durene[151] and the diacylation of anisole [*100-66-3*] with a mixture of glacial acetic acid and phosphorus pentoxide [152]:

Industrially applied examples of multiple acylation of aromatics can be taken from [153]. As is evident from Table 10, electron-donating substituents facilitate acylation, and the increase of reactivity by polysubstitution is impressive.

Table 10. Relative rate of benzoylation of substituted benzenes [154]

Substrate	Relative rate
Chlorobenzene	0.011
Benzene	1
Toluene	154
m-Xylene	3 910
Mesitylene	125 000
Pentamethylbenzene	139 000

Besides benzene and its derivatives, polynuclear carbocyclic aromatic compounds, such as naphthalene, diphenyl, anthracene, phenanthrene, and pyrene, also can act as substrates in acylation reactions. Electron-rich heterocycles, such as pyrrole, furan, and thiophene, as well as their polycyclic derivatives are especially activated, whereas pyridine and quinoline do not react unless activated by substituents. Non-benzenoid aromatic substrates active in acylation include azulenes, ferrocenes, and indolizines [148].

Table 9. Aromatic ketones by Friedel – Crafts acylation [115]

Acylating agent	Aromatic compound	Product	End use
Acetic anhydride	benzene	acetophenone	perfumes, pharmaceuticals, solvent, plasticizer
Acetic anhydride	toluene	4-methylacetophenone	perfumes
Acetic anhydride	anisole	4-methoxyacetophenone	perfumes
Acetic anhydride	isobutylbenzene	4-isobutylactophenone	pharmaceuticals
Dichloroacetyl chloride	1,2-dichlorobenzene	α,α,2,4-tetrachloroacetophenone	insecticides
Chlorobutyroyl chloride	fluorobenzene	chloropropyl 4-fluorophenyl ketone	pharmaceuticals
Tetrachloromethane	benzene	benzophenone	pharmaceuticals, insecticides, perfumes
Benzoyl chloride	benzene	benzophenone	
Phosgene	*N,N*-dimethylaniline	4,4′-bis-dimethylaminobenzophenone	dyes
Phthalic anhydride	benzene	2-benzoylbenzoic acid	anthraquinone

Although acylation has much in common with Friedel – Crafts alkylation, there are characteristic differences. For example, consumption of the acidic catalyst is usually at least stoichiometric. However, there are examples in the literature where substoichoimetric amounts of Lewis acids are applied. The course of the reaction is more uniform than in Friedel – Crafts alkylation, leading to higher regioselectivity. Also, isomerizations and other side reactions are rare.

Catalysts. Essentially the same catalysts as discussed for the Friedel – Crafts alkylation can be used. In most cases, the catalyst of choice is $AlCl_3$ [*7446-70-0*] [155], [156]. Impurities in $AlCl_3$, such as $FeCl_3$ or traces of water, enhance yields and the reactivity of systems, which otherwise react only slowly [157–159]. In some cases, however, the high activity of $AlCl_3$ leads to undesirable side reactions, for example, the decomposition of reactive heterocycles, such as benzofuran, decomposition of ethers, or rearrangements of alkyl groups [160]. In these cases, the activity of $AlCl_3$ can be moderated by complexing solvents such as nitrobenzene, which form 1 : 1 adducts. BF_3 and $SnCl_4$ are also suitable acylating catalysts for sensitive heterocycles.

If anhydrides, esters, or carboxylic acids are used as the acylating agents, strong proton acids, such as sulfuric acid, perchloric acid, orthophosphoric, and polyphosphoric acid also can be applied. Polyphosphoric acid, originally utilized mainly for intramolecular cyclization reactions, is also being used increasingly in intermolecular acylations.

As already mentioned (Chap. 1), the reaction of an acyl halide with an aromatic substrate, catalyzed by $AlCl_3$, results in a stable complex of the Lewis acid with the aromatic ketone, from which the product is liberated by hydrolysis. Thus, in contrast to Friedel – Crafts alkylations, the catalyst must be usually applied in at least stoichiometric amounts with respect to the acyl halide. Examples for the unusual use of substoichiometric ("truely catalytic") amounts of Lewis acids are ferrous chloride [161–164], zinc or iron oxides [165], cobalt chloride [166], and rare earth metal triflates [167–170].

R = alkyl, aryl

At least a twofold amount of catalyst is necessary if carboxylic acids or esters are the acylating agent, and in the case of anhydrides a threefold amount (but 1.5 mol per mole of product):

$$RCO_2H + 2\,AlCl_3 \longrightarrow RCO\text{-}Cl \cdot AlCl_3 + AlOCl + HCl$$

$$RCO_2R' + 2\,AlCl_3 \longrightarrow RCO\text{-}Cl \cdot AlCl_3 + AlOCl + R'Cl$$

$$(RCO)_2O + 3\,AlCl_3 \longrightarrow 2\,RCO\text{-}Cl \cdot AlCl_3 + AlOCl$$

R,R′ = aryl, alkyl)

A catalyst with industrial importance is hydrogen fluoride [171], [172], sometimes in the combination with boron fluoride [173]. This has the advantage of avoiding waste formation due to the possibility to recover the catalyst by distillation. This technology is used commercially for the acylation of isobutylbenzene to 4-isobutylacetophenone, an intermediate for ibuprofen, a large volume anti-inflammatory drug.

Heterogeneous Catalysts. Even if the classical Friedel–Crafts Synthesis with homogeneous catalysts is still the most important process for the preparation of aromatic ketones, it has several disadvantages:

1) The use of stoichiometric or even greater amounts of "catalyst" is often required because of the formation of stable complexes with the products. Lewis acids like $AlCl_3$ are rather reagents then catalysts and contribute to a great extent to the production costs. They must be washed out of the product and cannot be recycled.
2) The reaction system is very corrosive and requires expensive reactors and also an expensive equipment for the purification of the waste gas, which consists not only of HCl, but also of chlorinated hydrocarbons.
3) The catalyst has to be neutralized and disposed together with a large amount of wastewater.

For this reason, much work has been done during the last years to substitute the homogeneous catalysts by heterogeneous catalysts, which do not have to be supplied in stoichiometric amounts and are not corrosive and can be easily separated, without neutralization. They can also be recycled for several times or used in a continuous fixed-bed process.

Heterogeneous acylation catalysts have to be strong Lewis or Brønsted acids. Only few classes of solid acids are strong enough to catalyze this reaction. The most important classes are:

Zeolites
Modified clays
Solid superacids
Heteropolyacids
Proton or Lewis acids on a support
Nafion and Nafion like composites

Zeolites are microporous, crystalline alumosilicates with strong Brønsted or Lewis centers. For the acylation reactions especially medium-pore systems like H-ZSM-5 or large-pore systems like HY zeolite, beta zeolite, or mordenite have successfully been used. Nevertheless only electron-rich aromatic compounds like anisol, alkylbenzenes, furanes, benzofuranes, phenoles or naphthalenes are active enough to react on zeolites in the liquid phase at temperatures below 150 °C.

Zeolites provide not only active acid sites but also the possibility to perform *shape-selective acylations*. The geometry of the micropores can control the regioselectivity of the reaction.

Clays. Clay minerals are sheet silicates with alternating layers of alumina and silica separated by nonbonding sheets. For catalytic purposes these minerals have to be modified to increase the number of acid sites. There are two types of clay catalysts: acid-treated clays and ion-exchanged clays. Acid treatment of clays by H_2SO_4 or HCl removes part of the alumina and also some other naturally occurring cations such as Mg^{2+} or Fe^{3+} from the layers, so that negatively charged alumosilicate sheets are generated, which are electrically neutralized by protons. These Brønsted acid catalysts (like K10) are commercially used for an number of acid-catalyzed reactions. The other type of catalysts are supported reagents, which are prepared by exchanging these protons with Lewis acid cations such as Zn^{2+} or Fe^{3+}. Commercial catalysts of this type, like Envirocat, can be used for the preparation of benzophenones even with less active aromatic compounds.

Solid Superacids. According to the definition of Gillespie superacids are acids, that are stronger than 100 % sulfuric acids. They have a Hammett acidity value H_0 of < -12. A number of solids belong to this class of materials: sulfated oxides, supported Lewis acids, and supported liquid superacids. Only a small number of oxides produces superacid sites on sulfation, including ZrO_2, TiO_2, HfO_2, Fe_2O_3 and SnO_2. The acid sites are generated by treating an amorphous oxihydrate of these elements with H_2SO_4 or $(NH_4)_2SO_4$ and calcining the products at temperatures of 500–650 °C. During the calcination step, the oxides are transformed into the crystalline tetragonal phase, which is covered by a small number of sulfate groups. Instead of H_2SO_4 also H_2MoO_4 or H_2WO_4 can be used to activate the oxide.

Miscellaneous. A number of other classes of catalysts have been descibed for acylation reactions: Heteropolyacids, surface mounted acids (proton or Lewis acids on a support), and Nafion. None of them is in commercial use.

Solvents. The aromatic substrate itself, nonpolar solvents, such as CCl_4 or CS_2, or solvents of medium polarity, such as dichloromethane

or 1,2-dichloroethane, may be used. If $AlCl_3$ is used as the catalyst, heterogeneous systems are formed with these solvents. However, in such solvents as nitromethane or nitrobenzene, homogeneous solutions are obtained, and at the same time the reactivity is reduced because of complex formation. The choice of solvent also can influence the regioselectivity of the acylation [174]:

A hazard of this reaction is that the adducts of $AlCl_3$ and nitrobenzene tend to decompose explosively at elevated temperatures.

Acylation using an acyl halide – Lewis acid catalyst system usually is carried out according to one of the following procedures:

1) The acylating agent is added to a cooled solution or suspension of the catalyst in a solvent; the aromatic substrate then is added to the preformed acylating complex (*Perrier method*) [175]
2) All reactants are mixed and cooled, and the catalyst added slowly (*Elbs method*) [176]
3) The aromatic substrate is used as the solvent for the catalyst, and the acylating agent is then added slowly (*Bouveault method*) [177].

The Perrier method often is preferred, because a constant ratio of catalyst to acylating agent is maintained throughout the reaction.

If sulfuric acid is used as the catalyst, a large excess of the acid is needed, to which the reactants are added. In order to avoid ring sulfonation or aldolization reactions, the temperature should be kept below 100 °C.

Acylating Agents. The great versatility of Friedel – Crafts acylation is based on the fact that both the acylating agent and the aromatic substrate can be varied systematically and through a wide range. The reactivity of acylating agents follows roughly the following order:

$$[RCO]^+[BF_4]^- \approx [RCO]^+[ClO_4]^- > RCOO\text{-}SO_3H > RCOX > (RCO)_2O > RCO_2R' > RCONR'_2$$

Whereas the ionic acyl perchlorates and tetrafluoroborates are powerful agents, acid esters and amides are almost inactive in the absence of catalysts. The reactivity of the acyl halides decreases as follows: RCOI > RCOBr > RCOCl > RCOF.

However, the reactivity of acyl halides depends also on R, which may be alkyl or aryl and which can be substituted by halogen as well as by an alkyl, alkoxy, or a nitro group. The aromatic substrate and the type of catalyst also affect the reactivity [178], [179].

Aromatic acyl halides may well contain nitro substituents or be of the pyridine type, as in the synthesis of 3-benzoylpyridine [*5424-19-1*] from benzene and nicotinyl chloride [149]:

Bifunctional acyl halides also can act as the acylating agent. For example, the reaction of oxalyl chloride with a highly activated aromatic substrate, such as anisole, gives the corresponding benzil derivative [180]:

A commercially important reaction of phosgene is the reaction with *N,N*-dimethylaniline, yielding 4,4′-bis(dimethylamino)benzophenone (*Michler's ketone*) [*90-94-8*], which is used in the production of dyes:

Ketone formation can be avoided if one halogen of the phosgene is replaced by an amido group (R=H, alkyl):

The resulting amide can be hydrolyzed to the acid [181]. This reaction has been considered for an industrial synthesis of *terephthalic acid* [*100-21-0*] [182]:

Isocyanates, isothiocyanates, and CO_2 also can be used as acylating agents in the presence of $AlCl_3$ to give aromatic carboxylic acids or their derivatives [92].

If an unsymmetrical bifunctional acylating agent, such as an acid chloride containing an ester group, is used, only the more active acyl group reacts [183]:

Essentially the same products are obtained with the acid anhydrides, such as succinic, glutaric, or maleic anhydrides, in the presence of 2 mol of $AlCl_3$ per mole of anhydride [148]. By this method, 4-aryl-4-oxobutanoic acids can be obtained, which are intermediates in the Haworth synthesis of polynuclear aromatics [184].

A commercially important synthesis is that of *anthraquinone* [*84-65-1*] from phthalic anhydride and benzene [185] (→ Anthraquinone):

Under strongly acidic conditions, 3,3-diphenylphthalide [*596-29-2*] also can form. The synthesis of anthraquinone by this process is of special importance in the United States.

With zeolite catalysts, it is also possible to use nonactivated carboxylic acids. CHICHE found that higher fatty acids react in the liquid phase with toluene on Y-type zeolites to *p*-acyltoluenes with yields up to 96 % [186].

2.2.1. Acylation of Benzene and Benzene Derivatives

Acylation of benzene with acetic anhydride to give acetophenone [*98-86-2*] in 85 % yield was carried out commercially, using $AlCl_3$ as catalyst and keeping the temperature at 30 °C by cooling. Acetophenone is now produced industrially by the oxidation of ethylbenzene or of cumene (→ Ketones, Chap. 7.1.).

Benzene can be acylated with benzoic acid at elevated temperatures in the gas phase to give benzophenone [187]:

27% yield

Acylation of toluene, for example, using acetyl chloride and aluminum chloride, leads with 97.6 % selectivity to 4-methylacetophenone [*122-00-9*], which is used for the production of perfumes [188].

Acylation of Deactivated Substrates. Benzenoid aromatic compounds with nitro, carboxyl, nitrile, and acyl substituents that hinder electrophilic substitution can be acylated only if an activating second substituent, such as a hydroxy or alkoxy group, is present. Deactivated substrates like chlorobenzene can be acylated to *p*-chlorobenzophenones by use of commercial heterogeneous catalysts like zeolites or sulfated zirconia as solid superacids [189].

100% yield

Acylation of activated substrates, such as phenol, can be carried out using carboxylic acid – $ZnCl_2$, carboxylic acid – BF_3, or carboxylic acid – polyphosphorus acid as catalysts [190]. Up to 25 % selectivity of ortho substitution is observed for the acylation of phenols [191], and the ortho to para ratio depends strongly on the choice of catalysts and solvents.

Linear alkylphenols can be obtained via acylation followed by reduction. An example is the synthesis of *hexylresorcinol* [*136-77-6*], which is used commercially as a disinfectant [192]:

Both phenols and phenyl ethers belong to the most reactive substrates and therefore react under relatively mild conditions. For instance, anisole is acylated conveniently at 40 – 50 °C in the presence of polyphosphoric acid. Phenyl ethers are acylated almost exclusively in the 4 position.

A clean alternative to conventional Friedel – Craft acylation systems, which avoids formation of waste salts and byproducts, uses mixed anhydrides of trifluoroacetic acid which are formed in situ by reaction with carboxylic acids. Low concentrations of H_3PO_4 are used as the catalyst and trifluoroacetic acid is recycled after dehydration [193].

Acylation of Aromatic Amines. After N-acylation, aromatic amines react in a manner similar to alkylaromatic compounds in acylation reactions. Tertiary aromatic amines, such as *N,N*-dimethylaniline, can be acylated in the

4 position using P_2O_5 as catalyst, as is exemplified by the synthesis of Michler's ketone [194], [195].

Cyclization Reactions. The para-directing effect of substituents also is found here. 6-Methoxy-1-tetralone [*1078-19-9*] is obtained in 96 % yield from 4-(3-methoxyphenyl)butyric acid [196], [197]:

Important examples of intermolecular cyclizations are reactions of phthalic anhydride [*85-44-9*] with benzene and substituted benzenes to give *anthraquinone* [*84-65-1*] and substituted anthraquinones respectively (see bottom):

The reaction of phthalic anhydride with toluene or chlorobenzene leads, in a two-step process, to the 2-substituted anthraquinones, whereas the corresponding reaction with 4-chlorophenol gives 1,4-dihydroxyanthraquinone [*81-64-1*] (*chinizarine*) directly. Oxidation, nitration, chlorination, or amination leads to products that are important intermediates for fine chemicals. The Friedel–Crafts acylation of ethylbenzene with phthalic anhydride yields, in a two-step process, *2-ethylanthraquinone* [*84-51-5*], which is utilized in the synthesis of H_2O_2 [198].

2.2.2. Acylation of Polynuclear Aromatic Compounds

Acylation of naphthalene usually leads to mixtures of 1- and 2-acyl derivatives, the ratio of which depends mainly on the solvent used. Nonpolar solvents, such as CS_2 or CCl_4, favor acylation in the 1 position; polar solvents, such as CH_3NO_2 or $C_6H_5NO_2$, favor the formation of 2-acetylnaphthalenes [199].

Acylation of substituted naphthalenes often gives complex product mixtures. As a rule, acylation of the more highly activated ring is more likely to occur. However, it is possible to control the regioselectivity by the shape selectivity of zeolites. Thus, the acylation of 2-methoxynaphthalene on zeolite HY produces only 1-acetyl-2-methoxynaphthalene while on beta zeolite also 2-acetyl-6-methoxynaphthalene is formed [200].

1,5-Diacylation is possible only under more drastic conditions, as in the synthesis of *1,5-dibenzoylnaphthalene* [*83-80-7*]:

This compound can be fused in sodium aluminum chloride to give *dibenzopyrenequinone* [*128-66-5*], a dye commercialized as Indanthren Goldgelb GK [201].

If naphthalene reacts with diacyl compounds, the 1,8-diacylated products often form [202]:

Acylation of Biphenyls. If one ring of a biphenyl is deactivated by an electron-withdrawing substituent, the other ring can be acylated in the 4 position [203]:

Acylation of Anthracene [*120-12-7*]. In the presence of $AlCl_3$ and under mild conditions in nonpolar solvents (0 °C, benzene), anthracene is acylated at the most reactive 9 position. Isomerization of the ketone – $AlCl_3$ complex is prevented by precipitation. If polar solvents, such as nitrobenzene, are used, a mixture, consisting mainly of 1-acylanthracene and some 2-acylanthracene is formed [204]. Also in this case, 9-acylanthracene is probably the primary product, which is then isomerized [148]:

Acylation of Phenanthrene. Similarly, acylation of phenanthrene [*85-01-8*] in nitrobenzene yields mainly the 2- and 3-acyl isomers, whereas use of the less polar solvent dichloroethane gives the 9-acyl isomer as the main product [147], [204].

2.2.3. Acylation of Heteroaromatic Compounds

Because of their high electron density, furan, thiophene, and pyrrole are highly activated in

electrophilic substitution reactions and thus can be acylated under mild conditions.

Acylation of furan leads to high yields of the 2-acyl derivative, especially if anhydrides are used as acylating agents:

The high reactivity of furan [*110-00-9*] allows the use of benzene as solvent. Zinc chloride, boron trifluoride, and phosphoric acid also are suitable catalysts [205]. Acylation also can occur in the 5 position.

Acylation of Thiophene. The reactivity of thiophene [*110-02-1*] can be compared with that of anisole; the compound can be acylated in high yields utilizing acyl halides in the presence of $SnCl_4$ or anhydrides in the presence of phosphoric acid or $ZnCl_2$ as the acylating agent [206].

Acylation of pyrrole [*109-97-7*] may occur even in the absence of catalysts, although $ZnCl_2$, BF_3 , and $AlCl_3$ often are used with anhydrides as acylating agents [207]. Acylation usually occurs in the 2 position but 2,5-diacylation also is possible. 3-Acylation is observed only if the 2 and 5 positions are blocked.

Acylation of Imidazoles. Highly deactivated heterocycles, which can not be acylated in homogenous liquid phase like imidazole or pyrazoles react on Na-Y-zeolites at temperatures of more than 500 °C [208]:

Acylation of Benzofurans. With very reactive heterocycles acylations can be carried out using zeolites in a continuous liquid-phase process, for example the acylation of 2-methylbenzofuran with acetic anhydride [209]:

Acylation of Dibenzofuran [*132-64-9*], **Dibenzothiophen** [*132-65-0*], etc. Acylation or diacylation occurs in the 2 or 8 position (3 or 6 position in *carbazole* [*86-74-8*]) [210], [211]:

Miscellaneous. Substituted *4* H-*pyrones* have been acylated in excellent yields using trifluoroacetic acid as the catalyst. Even diacylation is possible [212]:

A large variety of further heteroaromatic compounds, such as chroman, xanthenes, 1,3-benzodioxole, and dibenzodioxins, have been acylated; for a review see [147].

2.2.4. Acylation of Nonbenzenoid Aromatic Compounds

Ferrocene [*102-54-5*] can be acylated readily by acyl halides in the presence of aluminum chloride, and its reactivity is comparable to that of phenols [213]. Besides acyl halides, anhydrides may be used as the acylating agent. Monoacylation of ferrocene is possible with BF_3 as catalyst [214]:

With an excess of acylating agent and of $AlCl_3$, heteroannular diacetylation occurs almost exclusively [215].

Other cyclopentadienyl derivatives also can be acylated and the reactivity of some aromatic substrates has been found to decrease in the following order [215], [216]:

$$C_6H_5OH \approx (C_5H_5)_2Fe > C_6H_5OCH_3 > CH_3C_5H_4Mn(CO)_3 > C_5H_5Mn(CO)_3 > C_6H_6$$

Azulene [*275-51-4*] reacts smoothly with acetic anhydride in the presence of $SnCl_4$ as catalyst; the cyclopentadienyl part is acylated, giving 1-acetylazulene. Under more drastic conditions and in the presence of $AlCl_3$ or $SnCl_4$, 1,3-diacetylazulene is formed using acetyl chloride or acetic anhydride as the acylating agent [217], [218].

2.2.5. Miscellaneous Acylation Reactions

Among the various reactions leading to aromatic C-acylation products, the formylation reactions, the Houben – Hoesch synthesis, and the Fries rearrangement are of importance.

Formylation of aromatic compounds is simply a special case of acylation and occurs when a formyl halide or formic anhydride reacts with an aromatic compound in the presence of a Friedel – Crafts catalyst, such as $AlCl_3$. However, the scope of this reaction is limited because of the instability of most formylating agents.

Gattermann – Koch Synthesis. A mixture of hydrogen chloride and carbon monoxide in the presence of $AlCl_3$ and copper (I) chloride is used as formylating agent for aromatic compounds [219]:

Benzene as well as substituted benzenes or polycyclic aromatics react in the Gattermann – Koch synthesis to give aromatic aldehydes. The *para* isomers are formed preferentially, and aromatic compounds with *meta*-directing substituents do not react in this formylation [220].

A modified Gattermann – Koch synthesis is being considered by Mitsubishi Gas Chemical for the industrial synthesis of *terephthalic acid.* Toluene reacts with CO and $HF-BF_3$ to give *p*-tolualdehyde in 96 % yield, which is then oxidized to terephthalic acid [221], [222].

More recent studies suggest that the acylating agent in these processes is in fact $[CHO]^+$, which is formed by protonation of CO or its complexes. An equimolar CO – HCl mixture as required for this reaction can be prepared as follows:

$$HCOOH + ClSO_3H \longrightarrow H_2SO_4 + CO + HCl$$

$$HCOOH + C_6H_5COCl \longrightarrow C_6H_5COOH + CO + HCl$$

Vilsmeier Aldehyde Synthesis [223]. Aromatic and heterocyclic substrates are formylated by reaction with dialkyl- or arylalkylformamides in the presence of $POCl_3$:

Besides anthracene, pyrene, acenaphthene, and other reactive polynuclear aromatic compounds, phenol ethers, dialkylamines, and *N*-heterocycles, such as pyrrole and indole, can be formylated. The regioselectivity of formylation follows the general rules of Friedel – Crafts reactions and leads usually to the 4-substituted aromatic compounds. Aromatic substrates also can be formylated by use of dichloromethyl methyl ether or trialkyl orthoformate in the presence of $TiCl_4$ or $AlCl_3$, respectively [224].

Houben – Hoesch Synthesis. This synthesis, which is related to the Gattermann reaction, uses nitriles to acylate reactive aromatic substrates, such as phenols, phenyl ethers, pyrroles, thiophenes, and indoles. The reactions are carried out in the presence of HCl and $ZnCl_2$ [225], [226]:

The active electrophile is the imminium ion, formed by addition of HCl to the nitrile and complexed by the Lewis acid. This bulky intermediate leads almost exclusively to acylation in the 4 position and not in the 2 position. Compared to the Friedel – Crafts acylation with acyl halides or anhydrides, the Hoesch synthesis is often more straightforward in the acylation of activated phenols.

Fries Rearrangement. For the synthesis of fine chemicals, the Fries rearrangement of aryl esters, which can be prepared by the acylation of phenols, is a useful method for making phenolic ketones:

The production of pharmaceuticals, such as adrenalon, synephrin, buphenin, and acebutolol, involves Fries rearrangements. Although the reaction tends to give mixtures of the ortho- and para-acylated phenol, the selective formation of each of the isomers is possible by controlling the reaction conditions [227]:

As a rule, para substitution is favored at low temperatures and ortho substitution at high temperatures, but regioselectivity also is affected by solvents and the nature and amount of catalysts.

Numerous substrates that can be substituted both in the phenol part and the acid part are reactive in this rearrangement. Even phenol derivatives containing electron-withdrawing substituents, such as the nitro group, react, as well as naphthol and hydroxy- or dihydroxyphenyl esters [228].

N-Acylanilines also can be rearranged to give 4-acylanilines at elevated temperatures [229]:

Similarly, the acid part can be varied and all types of alkyl or aryl acids have been used including some diaryl dicarboxyl esters. Sulfonic

acid esters also have been rearranged to give 4-hydroxyphenyl sulfones [230].

Usually, $AlCl_3$ is used as the catalyst, but $SnCl_4$, $TiCl_4$, $FeCl_3$, and $ZnCl_2$ are also active and in some cases more convenient. The rearrangement can be carried out by heating a mixture of the phenolic esters and the catalyst to 80 – 180 °C. Depending on the reactivity of the substrate, the reaction is complete within a few minutes or up to 3 or 4 h. The reaction can be carried out also at lower temperatures in a solvent, such as $C_6H_6NO_2$, $(CH_2Cl)_2$, CS_2, C_6H_5Cl, or petroleum ether. Fairly long reaction times must be used in this case. Another possibility is to start the rearrangement in CS_2, which is then separated by distillation, and to complete the reaction at higher temperatures [231].

The ortho isomer often can be separated from the product mixtures by steam distillation. Volatile products can be fractionally distilled. The para isomer can be separated from nonvolatile product mixtures by crystallization. A more detailed literature survey can be taken from [228, 232, 233].

3. Acylation and Alkylation of Aliphatic Hydrocarbons

Aliphatic hydrocarbons can be both alkylated and acylated, although industrially, alkylation is by far the more important reaction. Because of their nucleophilicity, reactions must be base or acid catalyzed. Base catalysis involves the formation of an organometallic derivative, whereas acidic catalysts lead to carbenium ions as active intermediates.

Acylation and Alkylation of Paraffins. Not very much work has been done on acylation and alkylation of pure paraffins; such reactions are known but never have gained much interest in industry for synthetic purposes [234]. However, the alkylation of toluene with propene to yield isobutylbenzene is carried out commercially at a multithousand t/a scale. Isobutylbenzene [*538-93-2*] is an intermediate for ibuprofen, a widely used anti-inflammatory agent:

In the presence of very strong acids, such as $HF-TaF_5$, alkanes also can be self-alkylated [235]. The reaction between a paraffin and an olefin [64] to produce a higher paraffin is thermodynamically possible at low temperatures and is exothermic. However, rate and selectivity are low, and side reactions occur. Good results are obtained if highly branched paraffins are introduced. The best known example is the alkylation of isobutane with olefins using acids as the catalyst. This reaction is used on a huge scale by the petroleum industry to make highly branched paraffinic hydrocarbons, which are excellent antiknock components for motor fuels (→ Automotive Fuels, Chap. 4.1.; → Oil Refining, Chap. 3.7.1.). The industrial processes in operation today use large quantities of liquid Brønstedt acids (HF, sulfuric acid). The handling of large quantities of these acids has created environmental and safety concerns. As an alternative, a fixed-bed alkylation process with a supported liquid phase (SLP) catalyst has been developed to the pilot plant stage [236], [237].

Alkylation and Acylation of Olefins. Formally, all oligomerizations and polymerizations of olefins can be considered as alkylation. Table 11 summarizes a few of these reactions. There are some similarities in reaction mechanism between Ziegler – Natta-type catalysts and acylation – alkylation catalysts.

Acylation of olefins may be considered a Friedel – Crafts reaction. The reaction usually occurs with derivatives of carboxylic acids in the presence of an acid catalyst. The Lewis acids, whose activities follow the order $AlCl_3 > BF_3 > SnCl_4 > ZnCl_2$, require anhydrous conditions and temperatures ranging from 0 to 100 °C. At elevated temperatures interfering side reactions can occur.

Table 11. Alkylation of olefins

Olefin	Catalyst	Product
α-Olefin (ethylene, propylene)	Ziegler-Natta ($AlR_3 - TiX_4$)	polymers
Ethylene	Ni chelate	α-olefins
1-Decene	BF_3	lubricants
	$NiX_2 - AlX_nR_m$	dimers (motor fuel, plasticizer, detergents)
Isobutene	H^+	dimers (motor fuel, solvents)
Propene	AlR_3	dimers, oligomers (isoprene, detergents)
Ethylene – butadiene	Rh complexes	1,4-hexadiene

The acylation of olefins with acid chlorides in the presence of aluminum chloride leads to β-haloketones and β-unsaturated ketones [238]:

Acylations of olefins have been commercially applied only for the synthesis of fine chemicals, such as the unsaturated ketone (**2**), Vertofix Coeur [*80449-58-7*], (International Flavors & Fragrances, Inc., USA), used in perfume:

2

4. *N*-Alkylation and *N*-Acylation

An alkyl or acyl group can be attached to the nitrogen atom of an amine in many ways. The particular method chosen depends on the nature of the alkyl or acyl group and the amine used. The products obtained are used mainly as intermediates in the production of detergents, dyes, plasticizers, pharmaceuticals, agricultural chemicals, antioxidants, and vulcanization accelerators.

4.1. *N*-Alkylation

Alcohols, alkyl halides, olefins, and carbonyl compounds react with ammonia or amines to give alkyl derivatives [64]. Further alkylation of a tertiary amine leads to formation of quaternary ammonium compounds, which have found broad application in detergents. For instance, selected amines are alkylated with 1,3-propane sulfonate or epichlorohydrin sulfonate, giving sulfobetaines:

Another derivative typical of this class is cetyltrimethylammonium chloride, made by exhaustive methylation of the primary amine with methyl chloride (→ Surfactants, Chap. 8.1.).

Among the best known "quats" are benzyldimethylalkylammonium chlorides (alkyl, e.g., dodecyl). These are made by methylating the primary amine derived from coconut oil to give the dimethylalkylamine, which is then quaternized by addition of benzyl chloride. The products are marketed as Zephirol, Roccal, Ammonyx, and Triton K 60. These compounds are used widely as disinfectants, antiseptics, and fabric softeners.

4.1.1. *N*-Alkylation by Alcohols or Ethers

Alkylations of amines with alcohols or ethers are of commercial interest. These alkylations are carried out at temperatures up to 300 °C and pressures up to 100 bar. Generally, acidic catalysts, such as HCl, H_2SO_4, BF_3, PCl_3, and H_3PO_4, are used in the liquid phase. In the gas

phase, Al_2O_3, $Al_2O_3 \cdot SiO_2$, or dehydrogenation catalysts are applied. The liquid-phase operation is hampered by severe corrosion problems. The reaction can be carried out in batch or continuous-flow operations. Mixtures of the possible NH-exchange reaction products are obtained. Some control is possible by varying the ratio of reactants and by recycling undesired compounds.

Methylamine, dimethylamine, and trimethylamine [*74-89-5*], [*124-40-3*], [*75-50-3*] are made by the reaction of methanol with ammonia in a continuous-flow system in the presence of a dehydration catalyst, such as aluminum silicate or phosphate, at 350 – 400 °C. All three possible methylamines are formed, but the product distributions can be controlled by reaction conditions (excess NH_3, addition of H_2O) and by recycling the trimethylamine (→ Methylamines).

Higher aliphatic amines, ethyl through pentyl, can be made by processes similar to that described for methylamines. Furthermore, such a reaction can be applied to make ethylenediamine from ethylene glycol.

Aromatic amines can be produced by this route using an acid as catalyst. However, starting from a secondary amine, it is not possible to make monoalkyl derivatives exclusively.

The alkylation of aromatic amines can be used for an efficient synthesis of *N*-methylaniline [*100-61-8*], *N,N*-dimethylaniline [*121-69-7*], *N,N*-diethylaniline [*91-66-7*], *N*-benzyl-*N*-ethyl-*m*-toluidine [*119-94-8*], *m*-chloro-*N*-ethylaniline [*15258-44-3*], *N*-benzylaniline [*103-32-2*], and other aromatic amines, many of which function as dye precursors. For instance, *N,N*-dimethylaniline [*121-69-7*] has been produced on a large scale since 1870 by the alkylation of aniline with methanol. Dimethyl ether can be used instead of methanol, as is known from a BASF process.

4.1.2. *N*-Alkylation by Alkyl Halides

The reaction of an alkyl halide with ammonia or an amine has long been used, particularly in the laboratory, to prepare alkylamines, although industrial processes also are based on this route. For example, pentylamines are made by mixing a solution of ammonia in alcohol with pentyl chlorides. By a similar reaction, ethylenediamine is produced from ammonia and 1,2-dichloroethane. No catalyst is required here.

The reaction of an amine with an alkyl halide is a versatile method for producing a variety of fine chemicals. Examples are the synthesis of sodium *N*-methylglycinate, which is used in the production of compounds (**3**) employed in the textile and cosmetic industries or as corrosion inhibitors, and that of *p-N*-methylaminophenol (**4**), used in the photographic industry.

4.1.3. *N*-Alkylation by Olefins

Alkylamines can be prepared by the direct addition of an olefin to ammonia or an amine using alkali metals as catalysts. This method works well with ethylene. For example, mono- and diethylanilines are prepared industrially from ethylene and aniline using alkali metals as catalysts.

Higher olefins also react, but amine yields are lower.

4.1.4. *N*-Alkylation by Carbonyl Compounds (Reductive Alkylation)

Alkyl derivatives can be obtained by the reaction of either ammonia or an amine with a carbonyl compound, such as an aldehyde or a ketone, in the presence of a suitable hydrogenation catalyst and hydrogen [239].

$$RCHO + R'NH_2 + H_2 \longrightarrow RCH_2NHR' + H_2O$$

Reductive alkylation is used commercially, for instance, to introduce branched alkyl groups (R′, R″).

Antioxidants, such as *N,N'*-di-*sec*-butyl-*p*-phenylenediamine [*101-96-2*], are synthesized by this route [240]:

A further example of importance to the dye industry is the synthesis of anilinoethanenitrile (**5**), which is an intermediate in the production of indoxyl (**6**) [*480-93-3*]:

4.2. *N*-Acylation

The acylation of NH groups occurs quite readily. The most common acylating agents are acyl halides, esters, anhydrides, and carboxylic acids.

R, R' = alkyl, aryl

Besides amines, many other compounds containing NH groups can be acylated. At high enough temperatures, even diacylation (for example, with primary amines) is possible. However, secondary amines react much more slowly than primary ones.

Acylation at the nitrogen atom often proceeds satisfactorily without a catalyst. This is especially the case for highly nucleophilic NH derivatives with electron-releasing substituents. Common catalytic procedures, if used, involve alkoxides (with esters as alkylating agents), sulfuric or phosphoric acid (with anhydrides or carboxylic acids), and aqueous alkali (with aroyl halides, Schotten – Baumann reaction).

Acylation is frequently used in the laboratory to separate tertiary from primary and secondary amines (Hinsberg reaction). After acylation of primary and secondary amines, the tertiary amines, which cannot be acylated, can be distilled.

Acylating Agents. The use of *carboxylic acids* requires the removal of water from the reaction mixture. This can be done by distillation in the presence of xylene, toluene, or chlorobenzenes. Sometimes catalysts, such as PCl_3, P_2O_5, or phosphites, are used.

Acyl halides often are preferred as acylating agents because they are easily prepared. An inert solvent often is used to precipitate the products. After filtration, the amine salt can be removed from the solid by washing with water. It is noteworthy that in this method half the amine is lost via salt formation. The HCl can be removed by Na_2CO_3, alkali (Schotten – Baumann reaction), or by adding other N bases. Among *anhydrides,* acetic anhydride plays an important role, but for economic reasons, industry prefers to use acids. *Esters* also have found wide application. They are especially suitable if the alcohols formed boil at lower temperatures than the N derivatives, thus removing the alcohol from the equilibrium.

Other acylating agents in use include aldehydes, ketones, ketenes, thiol esters, silicon tetraesters, carbamates, trihaloketones and aldehydes, acyl azides, amides, imides, and hydrazides.

***N*-Acylated products** and intermediates have found many applications, especially in pharmaceuticals, agrochemicals, dyes, and

polymers. N-*Acetylsalicylamide* [*487-48-9*] (**7**) and *p*-ethoxyacetanilide (*phenacetine*) [*62-44-2*] (**8**) are two representative examples of pharmaceuticals synthesized by N-acylation [241].

7

8

Amides of carboxylic acids with such generic names as propanil, monalide, chloranocryl, and allidochlor are used as herbicides [242]. Their synthesis is based on acylation of amines. *N*-Acylcarbamates, which can be synthesized by NH-acylation, are used as insecticides.

Two examples of dye precursors are *N*-(2-carboxyphenyl)glycine (**9**) and so-called "arylide" compounds (**10**):

9

10

N-Acylation to provide a protective group.

The primary NH group in aniline derivatives can be masked by acylating the compound prior to chlorination or nitration. For this purpose, acetanilide, *N*-acetyl-*o*/*p*-toluidine, *N*-acetyl-*o*/*p*-anisidine, *N*-acetyl-*p*-phenetidine, and *N*-acetyl-*p*-aminophenol are prepared as intermediates. The acetyl group can be removed by heating in NaOH. The following reaction is used in the pharmaceutical industry to synthesize *sulfonamides* [241]:

Protection of amine functions is also important in peptide syntheses.

5. *O*-Alkylation and *O*-Acylation

The following types of reactions can be considered:

Reactions in which the hydroxyl group is attacked are very wide ranging. However, those alkylations or acylations in which the OH group is attached to a carbon atom are of greatest industrial importance. Table 12 enumerates reactions

and reaction products involving alkylation and acylation of hydroxyl groups attached to carbon.

Table 12. Products of alkylation and acylation of alcohols and carboxylic acids

Alkylation/acylation agents	ROH	RCOOH
RCOX ∗, $(RCO)_2O$	esters	anhydrides
RX ∗	ether	esters
Olefin	ether	esters
∗ X=halide.		

Besides acyl halides, anhydrides, alkyl halides, and olefins, a variety of other alkylation and acylation agents are utilized. Although of minor industrial importance, alkylation with dialkyl sulfates or diazo compounds is a common laboratory method for preparing ethers and esters [243]. The commercial synthesis of *N*-acylcarbamates is based also on an O-alkylation:

5.1. Synthesis of Esters

Esters can be prepared by three routes: acylation of alcohols, reaction of acids with alkyl or aryl halides, and reaction of acids with olefins (see Table 12). The most readily available acylating agents are selected, together with appropriate catalysts where required. For acyl halides, such bases as pyridine or aqueous alkali are the preferred catalysts; for anhydrides, sodium acetate, sulfuric acid, and BF_3 are preferred. Many fine chemicals, such as pharmaceuticals, are made by this route. The synthesis of *acetylsalicylic acid* (aspirin) using acetic anhydride is an example:

Cellulose Acetate. An ester process of great industrial importance is the synthesis of cellulose acetate for synthetic fibers. Cellulose is added to equal amounts of acetic anhydride and glacial acetic acid, together with a small amount of sulfuric acid as catalyst. The acylation temperature is kept below 30 °C. After 5 – 8 h, water is added to the cellulose triacetate. The hydrolysis is stopped when the required degree of acetylation is reached by running the mixture into a large volume of water followed by centrifuging. For further details, → Cellulose Esters, Chap. 2.1.3.

Direct Esterification Using Olefins or Acetylene. Esters are formed also by alkylation of acids by olefins, but this method often is limited by low catalyst efficiency. Olefins ranging from ethylene to octenes and higher olefins can be used, together with such catalysts as BF_3, $BF_3 \cdot ROR$ (R = alkyl, aryl), or $BF_3 - HF$. Polymerization of reactive olefins often limits this application. The direct esterification of organic acids with olefins has distinct advantages from a processing standpoint over the two-step process in which the olefin is first hydrated to an alcohol with the acid.

Some of these processes are in industrial use. The reaction of α-pinene with carboxylic acids yields bornyl esters that are intermediates in camphor chemistry. Of industrial importance are also the vinyl esters of higher carboxylic acids (fatty acids, Koch acids) which are used as comonomers in polymerizations of vinyl chloride, vinyl acetate, acrylonitrile, styrene, and other compounds. The process is based on the reaction of the acids with acetylene in the liquid phase at 150 – 170 °C at 10 – 15 bar pressure.

As catalysts, zinc salts or $H_2O - H_2SO_4$ can be used.

5.2. Synthesis of Anhydrides

The acetylation of a carboxylic acid by RCOX yields an anhydride. By this route, unsymmetrical anhydrides can be prepared. Besides acyl halides, amides, esters, and acids, ketenes also can be used. The ketene reaction is of importance for the commercial synthesis of acetic anhydride and a convenient laboratory route to acetic carboxylic anhydrides:

$$RCOOH + CH_2{=}C{=}O \longrightarrow RCOOCOCH_3$$

5.3. Synthesis of Ethers

Ethers can be formed by the alkylation of a metal salt of an alcohol with an alkyl halide (*Williamson synthesis*). The reaction proceeds cleanly with active primary halides and often also with secondary halides. Tertiary alkyl halides are subject to an elimination reaction and are therefore unsuitable for the preparation of tertiary alkyl ethers. The alkyl chlorides are less reactive than the bromides or iodides, but for economic reasons the chlorides are favored for large-scale operations.

Ethers are produced in industry by the reaction of an olefin with an alcohol. This reaction is catalyzed by such acid catalysts as H_2SO_4, ion-exchange resins, phosphoric acids, or zeolites. The reactivity of the olefin decreases with increasing molecular weight: Isobutene reacts more readily than 2-methyl-2-butene. Best results are obtained with olefins containing tertiary carbon atoms because secondary olefins require higher temperatures and catalyst concentrations. Primary alcohols are more suitable than secondary alcohols for this reaction.

Methyl *tert*-butyl ether [*1634-04-4*] (MTBE), an ether of significant commercial interest, is used as an additive in gasoline. It is produced by the reaction of isobutene with methanol, applying an acidic catalyst, such as an anion-exchange resin. Several processes have been developed by Chemische Werke Hüls (now Degussa-Hüls), SNAM Progetti, Atlantic Richfield Co. (Arco), and Sun Oil Co. World capacity is estimated at 12×10^6 t/a for 1992 and 16×10^6 t/a for 2000. The C_4 fraction of naphtha crackers, which is free from butadiene (raffinate I), can be used directly as olefin feed. A liquid-phase system operating at $<100\,°C$ is used (→ Methyl *tert*-Butyl Ether).

Vinyl Ethers. The industrial processes for vinyl ether are based on the reaction of alcohols with acetylene:

$$ROH + HC{\equiv}CH \longrightarrow ROCH{=}CH_2$$

The reaction is carried out in the liquid phase at 120 – 180 °C with alkali hydroxides as catalysts. Low-boiling alcohols require the use of pressures up to 20 bar. Vinyl ethers are used for special polymers, coatings, and adhesives. Of industrial interest are methyl, ethyl, isopropyl, butyl, isobutyl, and 2-ethylhexyl vinyl ethers (→ Vinyl Ethers).

6. *CH*-Alkylation and *CH*-Acylation of Nonaromatic Compounds

Carbon-hydrogen bonds adjacent to electron-attracting groups such as nitro, carbonyl, cyano, sulfone, or phenyl can be C-alkylated or C-acylated [244–246]. The acidity of the C-H bond depends on the nature of the activating group. Procedures that involve the formation and subsequent reaction of anions derived from active CH compounds constitute a very important and synthetically useful class of organic reactions. Examples are the Dieckmann reaction, the Stobbe condensation, the Michael addition, the Claisen condensation, and the Thorpe reaction.

CH-Alkylation and -acylations have been used widely in the laboratory and for the synthesis of many fine chemicals. Generally, a carbanion is formed by hydrogen atom exchange with a base followed by reaction with the alkylation or acylation agent. Bases used are, e.g., sodium alkoxide and sodium amides.

R, R' = alkyl, aryl; Y, Z = electron-withdrawing groups; X = halide

7. Synthesis of Metal Alkyls

The direct alkylation of elements by alkyl halides is frequently the first stage in the synthesis of a variety of organometallic compounds. Especially the main-group metals yield stable derivatives that have found many industrial applications.

In 1900, Grignard discovered that the reaction of magnesium with alkyl halides leads to alkyl – magnesium – halogen compounds, RMgX. Today, Grignard compounds are standard laboratory chemicals.

$$RX + Mg \longrightarrow RMgX$$

Organolithium compounds can be prepared by the direct reaction of alkyl halides with lithium. Large quantities of butyllithium, which is used primarily as an initiator in the polymerization of dienes, is produced by this method.

The scope of organometallic compounds for CH-alkylations is broad and has found many applications, especially in the laboratory. Examples are the following well-known reactions:

Organometallic compounds also can be prepared by reacting metal hydrides with olefins.

$$AlH_3 + 3\,H_2C{=}CH_2 \longrightarrow AlEt_3$$

Numerous alkylations by transition metals have become known since the 1960s [40] and are gradually becoming accepted in chemical industry, especially for the synthesis of fine chemicals.

Examples of elemental acylation are rather rare and are of no practical importance as yet. However, some interest, especially among fine chemicals, is developing around the use of R–CO–M compounds to control regio- and stereoselectivity in acylations [247].

Aluminum Alkyls [248]. Alkylaluminum derivatives have gained considerable importance since 1953 when ZIEGLER reported their catalytic activity for polymerization and means of their preparation. Their consumption in the USA, Western Europe and Japan was estimated at 30 000 t in 1996.

The method of preparation depends on the particular alkyl derivative but generally involves one of the following alkylation reactions:

$$Al_2Mg_3 + 6\,RCl \longrightarrow 2\,AlR_3 + 3\,MgCl_2$$

$$AlH_3 + 3\,\text{olefins} \longrightarrow Al(\text{alkyl})_3$$

$$2\,Al + 3\,RX \longrightarrow RAlX_2 + R_2AlX$$

The most important derivative is $Al(C_2H_5)_3$ [*97-93-8*], the synthesis of which is based on the reaction of $Al(C_2H_5)_3$ with aluminum, hydrogen, and ethylene. Aluminum alkyls are used for the preparation of Ziegler – Natta-type catalysts, in the polymerization of olefins, and in the alfen and alfol processes for the production of α-olefins and alcohols, respectively.

Aluminum alkyls also are used industrially to synthesize other organometallic compounds, for instance R_4Sn:

$$3\,SnCl_4 + 4\,R_3Al \longrightarrow 3\,R_4Sn + 4\,AlCl_3$$

Organic Silicon Compounds. The direct reaction of silicon with alkyl or aryl halides (*Rochow reaction*) is used for the industrial synthesis of organosilicons:

$$2\,RX + Si \longrightarrow R_2SiX_2$$

The process takes place at high temperature in the presence of a catalyst, such as Cu, Ag, or Zn. Of the silicon derivatives produced, $(CH_3)_2SiCl_2$ [*75-78-5*] dominates the market. It is made by the reaction of silicon with CH_3Cl at 260 – 320 °C, catalyzed by copper. Besides $(CH_3)_2SiCl_2$ (70 – 90 % of the products), all other possible $(CH_3)_xSiCl_y$ compounds are formed in this reaction. The heterogeneous gas-solid reaction can be carried out in a fixed-bed or fluidized-bed reactor. For further details, see [249] and → Silicon Compounds, Organic.

Two other silicon derivatives, $(C_6H_5)_2SiCl_2$ and $C_6H_5SiCl_3$, have some economic importance. Besides the direct synthesis, the addition of Si-H to olefins is used to make silicon derivatives.

Lead Alkyls. Tetraethyllead [*78-00-2*] and tetramethyllead [*75-74-1*] are added to motor fuels to improve the octane number. However, for environmental reasons their use is now limited or banned. In 1977, world production was ca. 700 000 t, ca. 500 000 t in 1980, and 60 000 t in 1998 (USA, Western Europe and Japan). The sole use is in aviation turbine fuels.

Tetraethyllead is made by the reaction of lead – sodium alloy with ethyl chloride.

$$4\,NaPb + 4\,C_2H_5Cl \longrightarrow Pb(C_2H_5)_4 + 3\,Pb + 4\,NaCl$$

A catalyst is not required, but to speed up the reaction, 1 – 2 % acetone is added. Yields of up to 90 % are obtained [250] (→ Lead Compounds). Tetramethyllead is made by a similar route.

1. Introduction

Adhesives are defined as nonmetallic substances capable of joining materials by surface bonding (adhesion), the bond itself possessing adequate internal strength (cohesion). Adhesive is a generic term and covers other common terms, such as glue, paste, gums, adhesive cement, and bonding agent.

History. Adhesion is among the oldest technologies of mankind [129]. As early as the Stone Age, our ancestors made stone axes and other tools using mineral pitch or wood rosin. Asphalt was used in building the Tower of Babel. In ancient Egypt, it was already customary to veneer furniture with the aid of animal glues. Flour- and casein-based adhesives were applied in ancient Rome. Adhesives of plant origin such as wood rosin were as well-known in China, as was the gum arabic and the caoutchouc ("weeping wood") from the tropical regions of South America and Asia.

In the Middle Ages, the first glue-boiling plants came into being and produced protein glues from animal raw materials (glutin from hides and bones, blood albumin, casein from milk) or starch paste from plants.

With the developments in chemistry in the early 1900s, the technology of adhesives began to boom. Phenolic resins (ca. 1900), melamine resins, and urea resins (ca. 1930), polymer dispersions, epoxy resins (1938), and cyanoacrylates (1957) largely superseded the classic natural adhesives and, with a multitude of bindings agents, form the basis for modern adhesive technology, which is one of the most advanced joining processes.

Composition. An adhesive is composed of basic raw materials, which are called binders [1] and which determine its adhesiveness (adhesion) and its internal strength (cohesion), and of frequently necessary auxiliaries, which establish particular end-use and processing characteristics. The adhesiveness of an adhesive, its internal strength after setting, and its processing characteristics are the fundamental properties that determine its suitability for use in forming adhesive joints. Adhesive joints are the joints formed between substrates and adherents using adhesives.

The binders used for adhesives are primarily high polymers having optimal strength properties. High internal strength (cohesion) is essential if the adhesive in an adhesive joint is to be able to transmit forces from one adherent to the other. Most adhesives contain high molecular mass organic substances as their basic raw materials or reactive organic compounds that are preliminary stages of polymers and that react during the bonding process to form polymers. Inorganic polymers, such as the various types of waterglass, are used only to a very limited extent.

Virtually any standard polycondensate, homopolymer, and copolymer and also polyadducts may be used, provided they can be applied as solutions, dispersions, emulsions, or melts. In addition to these raw materials, auxiliaries such as resins, plasticizers, fillers, thickeners, solvents, antiagers, preservatives, hardeners, or setting retarders, are required, depending on the end use. Their function is inter alia to adjust tack, to improve adhesion, to make flexible, to regulate viscosity, to stabilize, and to influence setting or hardening.

Adhesive Joints. In many cases, adhesion is as effective as other joining techniques, such as riveting, welding, soldering, and screwing; in some cases it complements those techniques, and frequently it affords numerous advantages. On the other hand, certain processing requirements and material properties related to chemical structure can restrict the use of adhesives.

Bonding has the advantage that the joining of adherents can be carried out very rationally, often extremely quickly, and particularly economically [2]. One important feature common to all adhesive joints is the highly uniform distribution of forces over the entire joint area by comparison with rivet and screw joints. The uniform stress levels frequently provide for more optimal utilization of material strength. Accordingly, thinner and hence lighter sections of material may be used. This has resulted in the saving of material and, for example, in the automotive, aircraft, manufacturing, and furniture industries, in totally new structural elements (sandwich elements).

The use of adhesives enables numerous materials, even those differing widely in type, to be joined to one another. This applies above all to materials that cannot be joined to one another by other techniques. Because some adhesives set even in relatively thick layers, any unevenness in the constituent material of the adherents may be smoothed out during bonding, or significant dimensional tolerances may even be bridged by the gap-filling principle. The adhesive layer of an adhesive joint even may have a vibration-dampening effect and, by virtue of its insulating properties, can prevent contact corrosion in adhesive joints involving metals of different normal potential. Another advantage is the fact that many adhesives can be applied at room temperature or, when heat must be used for application, it is sufficient to apply temperatures at which the constituent materials of the adherents are not affected, as can happen in the welding of metals and plastics.

The usability of adhesives can be restricted when stringent requirements are imposed on the thermal stability of an adhesive joint [2]. Like all plastics, adhesives based on organic polymers also show a marked dependence on temperature in their strength properties. The strength properties of an adhesive joint can be kept constant and sufficiently high in only a relatively narrow temperature range. Adhesives cured by thermal cross-linking which are still relatively temperature resistant are generally capable of withstanding temperatures of up to about 150 °C. Using new, but more difficult to apply adhesives based on polyimides [3], it is possible to form adhesive joints which are capable of withstanding temperatures of the order of 250 °C for long periods. On the other hand, some adhesives, when subjected to heavy static stress for long periods, show a tendency even at room temperature to creep, a plastic deformation that can result in separation of the adhesive joint.

2. Adhesion Theories

The atoms or molecules in any solid are held together by so-called cohesion forces. These interatomic and intermolecular forces are conservative in character, i.e., not dependent upon the pretreatment of the material [4, p. 1]. After a break in the solid, the two fragments cannot be put back together in such a way as to restore the solid to its original state. Reactivation of the cohesion forces would be possible only if the original intervals between atoms or molecules could be reestablished. The same may be said also of the joining of two different materials; a mutual convergence over the entire joint area on the radius of interaction of the molecules would result in adhesion of the same order of magnitude as the cohesion forces [5]. In practice such convergence is not possible. There are three reasons for this: first, the surface roughness of the adherents; second, a reduction in the effective surface for boundary layer reactions due to the surface tension of the adhesive; and third, the formation of the so-called weak boundary layer [130], [131]. This is a region within the adhesive film close to the boundary layer where the reactive groups of the molecules are directed to the adherent and consequently do not contribute to the curing process, that is, no cross-linking occurs. Therefore, the weak boundary layer is always a weak link in the adhesive joint. The function of the adhesive in the boundary zone is to compensate for the effects of surface roughness by providing optimal wetting of the adherents.

Over the years, several different theories have been developed as to the mode of action of adhesives, i.e., the mechanism of adhesion. They

extend from the simple mechanical theory via the electrostatic and adsorption theory to the diffusion theory, these being the most important [6]. One feature common to all these theories is that, for some adhesion phenomena, these theories allow qualitatively satisfactory assertions to be made, but in other respects they fail totally and, in some cases, even lead to conflicting results. The adhesion of adhesive to an adherent, on which any joint is based, is clearly not a consistent and isolatable process [7] but a complex addition of various adhesion effects. Because the number of individual processes involved, apart from exceptions, is extremely difficult to estimate, definitive confirmation or rejection of individual theories is hardly possible.

Mechanical Theory of Adhesion. The oldest theory of adhesion is definitely the mechanical theory. It is based on mechanical anchorage of the adhesive in pores and irregularities in the adherent and is discussed primarily in reference to wood and similar porous materials [8].

Electrostatic Theory of Adhesion. According to the electrostatic theory [9], the adhesion forces between adherent and adhesive layer are applied by contact or transfer potentials. These transfer potentials cause the buildup of an electric double layer at the adhesive – adherent boundary and corresponding Coulomb attraction forces between the two components. In principle, the occurrence of transfer potentials is unquestionable, as shown by the electrostatic discharges that can be detected in the destruction of adhesive joints. However, the practical significance of the attraction forces associated with these discharges is still being debated [4, pp. 150 – 153], [10].

Adsorption Theory . As its name indicates, this theory of adhesion draws upon surface forces for explaining the observed phenomena [11]. It regards adhesion as essentially a special property of phase interfaces. The forces that are responsible for adhesion in this process are the so-called secondary valence or van der Waal's forces. These forces have three components, namely Keesom's dipole orienting effect, Debye's induced dipole effect, and London's dispersion effect [12–14]. For these forces to become active, the distances between the molecules of adhesive and adherent must converge toward molecular intervals. This requires complete spreading of the adhesive over the surface of the adherent. Good adhesion can be expected if the adhesive (in liquid form or in a liquid medium) wets the adherent [8]. Accordingly, the adsorption theory may be placed on an entirely thermodynamic basis. Adhesion is thus determined by the ratio between the surface energies of the adhesive and the constituent material of the adherent in the sense that the specific surface energy of the adhesive must be lower than that of the adherent. Accordingly, materials having high surface energy levels, such as metals, and those having medium surface energy levels, such as wood and paper, may be bonded relatively easily. In the case of polymers, bonding becomes increasingly more difficult [15], and finally almost impossible as surface energy decreases (polyolefins and polytetrafluoroethylene). The remedial surface treatment of materials such as these may be interpreted as increasing their surface energy [16].

The adsorption theory also shows that the adhesion forces of two materials are not reciprocal. For example, if a liquid epoxy resin adhesive is allowed to set on the surface of polytetrafluoroethylene or polyethylene, a very weak adhesive joint is formed. If, by contrast, liquid polytetrafluoroethylene or polyethylene is applied to the surface of hardened epoxy resin, strong adhesive joints are obtained [17]. In practice, this theory is not free from contradictions either; above all, it does not answer the question whether the difference in the surface energies between two materials is indicative of the intensity of the adhesion force [18].

Diffusion Theory. The diffusion theory of adhesion is essentially applicable to the bonding of high polymers. According to this principle, adhesion is obtained by the mutual penetration of adhesive and substrate [19], [20]. This mobility is based on the fundamental properties of high polymers: their chainlike structure and resulting mobility, allowing the possibility that the chains possess Brownian molecular movements in a submolecular range. By virtue of their greater mobility, the adhesive molecules normally play a greater part in the diffusion process. However, if the adhesive is in solution, which is generally the case, and if the substrate is slightly soluble in

the solvent, substrate molecules or parts thereof also diffuse into the spread adhesive. A diffusion bond is characterized by the disappearance of a clear boundary between the two phases and by the development of a gradual transition from one phase to the other. The mechanism of adhesion has developed into a three-dimensional process and is no longer confined to one interface.

The interdiffusion of the polymer molecules of adhesive and substrate is dependent upon various parameters, such as pressure, time, temperature, molecule size, and, of course, the reciprocal solubility, as shown by the correlation between the compatibility of the polymers and the quality of the bond [21]. Examples of bonds to which the diffusion theory is applicable include the bonding of PVC-U adherents to PVC in solvents containing tetrahydrofuran and so-called contact bonding, where the diffusion process takes place between two adhesive layers and not between adhesive and substrate [22].

The limits of the diffusion theory of adhesion show up in the adhesion of polymers, for example, to metal or glass. In this case, this theory does not make any useful contribution to the understanding of adhesion.

Other Theories. In addition to these theories, some special cases are discussed in the literature. They include *adhesion through primary valence forces,* for example, in the bonding of metals [8], [23], and so-called *liquid adhesion.* In the latter, a thin film of a liquid of extremely high viscosity produces adhesion through a process in which separation of adherent and substrate results in a flow in the narrow gap which is only possible by overcoming considerable resistance. Liquid adhesion is particularly assumed in pressure-sensitive bonding [16] and in the initial tack of a liquid adhesive.

Summary. None of the theories covers every single aspect of bonding. A promising combination of the theories to bring about an improvement does not exist at present. In addition, the theory of adhesion as a physicochemical phenomenon and physically measurable adhesion are generally still a considerable distance apart, so that the adhesion theories are only reference points. Secondary factors, such as surface roughness, boundary layers with faults (atmosphere, impurities), joint design, type of stress, and aging also influence bond strength to a considerable extent.

3. Definitions

Some of the terms are defined in DIN 16920 [24] and EN 923 [132].

Adherent: a body that is or is intended to be bonded to another body.

Adhesion: state in which two surfaces are held together by interfacial bonds.

Adhesive application: the application and distribution of an adhesive over the surface to be joined.

Adhesive coat: adhesive layer applied to an adherent.

Appearance of separated surfaces: surfaces formed in the event of failure of an adhesive joint; they provide information on the reason for the failure. Distinctions can be drawn visually between:

1) A bond layer that does not cover the entire joint area (uneven adhesive application)
2) Adhesion failure: rupture of the bond layer from the surface of the adherent
3) Cohesion failure: break in the bond layer
4) Insufficient coalescence: separation of two adhesive layers at the interface, for example, in the case of contact adhesives
5) Rupture of the surface layer of an adherent, breakage of the adherent (material failure)

In many cases, several types of failure occur together.

Assembly time: interval between application of adhesive to the adherents and the initiation by heat and/or pressure of the setting process in the assembled joint.

Application weight, spread of adhesive, coverage: quantity of adhesive applied per unit area of a surface. A distinction is drawn between wet application (including solvent or dispersant) and dry application (100 % adhesive). Each

type of adhesive has technically and economically an optimal application weight. In principle, rough and porous substrates (paper, fabrics) require more adhesive than smooth surfaces (glass, metals, films) to obtain whole-surface wetting and bonding. Application weights range from 1 g/m^2 (for example, for bonding films) to several 100 g/m^2, depending on the substrate, the method of application, and the type of adhesive.

Bond layer thickness: the thickness of the set layer of adhesive in millimeters. It may be influenced by the application weight and the fixing pressure. In general, a thin (< 0.001 mm) and uniform bond layer leads to the highest bond strengths.

Bond line: adhesive layer in a bonded joint.

Bond strength: force necessary to bring an adhesive joint to the point of failure in or near the plane of the bond line.

Closed assembly time: interval between assembly of the adhesive joint and the initiation by heat and/or pressure of the setting process in the assembled joint.

Cohesion: state in which the particles of a single substance are held together by primary or secondary valence forces.

Cold flow: deformation of an adhesive layer (or film) at room temperature without external applied load.

Creep: slow inelastic deformation of an adhesive layer under load following initial instantaneous elastic or rapid deformation.

Curing: the setting of an adhesive by chemical reaction (polymerization, polycondensation, polyaddition).

Heat resistance: the maximum temperature that a set adhesive in a joint is capable of withstanding. It depends upon the nature and intensity of the load and must be determined in each individual case.

Initial tack: the ability of a setting adhesive to hold two substrates together immediately after they have been joined. At this stage of the bonding process, strength is determined largely by rheological properties and depends on the cohesion of the unset adhesive. In the case of hot-melt adhesives, the analogous term "hot tack" is used, and this property is determined by the viscosity of the unsolidified melt. The transitions between the use of the terms initial tack and tack are fluent.

Minimum film-forming temperature: the temperature at which an emulsion-based adhesive just no longer dries to form a clear, homogeneous film.

Open assembly time, open time: interval between adhesive application to the adherents and assembly of the adhesive joint. The expression "open time" also is used occasionally for the period of time that elapses in a machine between application of the adhesive and bonding.

Primers: (mixtures of) substances that are applied before the adhesive to one or both of the surfaces to be joined, for improving adhesion and/or durability of the bond.

Setting: process by which an adhesive develops its cohesive strength and hence the physical and chemical properties of its bond.

Setting rate: the increase in strength in the bond line per unit time. It depends upon the setting mechanism and temperature and also may be influenced by the substrate (absorbency), bond layer thickness, etc. The setting rate generally is not constant and decreases toward the end of the setting time.

Setting time: time between joining of the adherents and the setting of the adhesive. It varies from a few seconds to several days, depending on the type of adhesive.

Shear strength: force per unit surface area necessary to bring an adhesive joint to the point of failure by means of shear forces.

Shelf life, storage life: time of storage under stated conditions during which an adhesive can be expected to retain its working properties. Appropriate storage generally is understood to mean that the adhesives are stored in clean, hermetically sealed containers and in cool, dry, well-ventilated rooms. Shelf life is largely dependent upon temperature. Aqueous and in some cases even solvent-containing systems have a tendency for skin formation, separation, and an increase in viscosity, particularly when stored for long periods at relatively high temperatures. They also can be spoiled by microbial attack. Wide fluctuations in temperature (freeze/thaw) lead to coagulation. Shelf lives of less than 12 months generally are indicated on the packing. Manufacturer's instructions should always be followed.

Tack: property of a material that enables it to form a bond immediately on contact with another surface, which can be an adherent or another layer of adhesive. High tack is particularly important in the case of pressure-sensitive adhesives (tapes, labels), for which it is even measured. Tack is generally difficult to measure in setting adhesives.

Thixotropy: decrease in apparent viscosity under shear stress, followed by a gradual recovery when the stress is removed. Thixotropic behavior allows pasty adhesives, for example, to be spread readily and applied in relatively thick layers, in some cases even on vertical surfaces, without running or flowing out of the gap before bonding because the adhesive loses its fluidity immediately after application.

Viscosity: property of a material to increasingly resist deformation with increasing rate of deformation. This property is quantitatively defined as dynamic viscosity or coefficient of viscosity and is often used synonymously with apparent viscosity. The viscosity of adhesives is primarily determined by means of rotational or throughflow viscometers (DIN cup, Ford cup, Zahn cup). Adhesives generally show non-Newtonian behavior. In addition to temperature, any expression of viscosity must also refer to the measuring instrument and measurement parameters (rotating spindle, rate of shear, nozzle diameter).

Working life, pot life: period of time during which a multicomponent adhesive can be used after mixing the components. The pot life of a given system depends primarily on the initial temperature of the mixture and on the quantity used (a high temperature and large quantities result in shorter application times), although it also depends on the mixing conditions (with or without cooling, type of stirrer used), on the ratio of surface area to volume of the mixing vessel, and on the method used for end-point determination. Moisture-curing single-component adhesives also can have a working life, which begins with the contact of atmospheric moisture with the adhesive and which, apart from temperature, is largely dependent upon the existing humidity and upon the degree of moisture uptake during stirring operations.

Standards: comparisons of ASTM, MIL, GB, ISO, and DIN standards can be found in [25] and [26].

Legal Regulations. In view of the formulation of adhesives, particularly the solvent content, their manufacture, packaging, storage, transportation, and application are governed by a large number of regulations, which concern generally goods containing inflammable, explosive, or physiologically harmful constituents. Clean-water and clean-air regulations also must be observed.

4. Raw Materials for Adhesives

The adhesives industry uses many different products of natural and synthetic origin. These are mainly raw materials that are produced in large quantities and hence at reasonable prices. Raw materials that are used solely or primarily for adhesives are relatively rare or, alternatively, represent special types within fairly broad production programs.

Basic raw materials are natural and synthetic polymers or monomers and prepolymers which can form such polymers. The polymers primarily impart the required strength (cohesion) to the adhesive layer. In many cases, however, they have adequate adhesion properties of their own.

The adhesion properties may be improved by addition of resins or special adhesion promoters. Plasticizers and resins improve the flexibility of the polymers, increase the tack of the adhesives, or establish other required product properties, e.g., rheological properties. Rheological and other special properties can be influenced by adding fillers. Polymers are often dissolved in water or an organic solvent to achieve the wetting necessary for good adhesion.

The required service properties frequently can be obtained by using different basic raw materials or different kinds of formulations. Accordingly, the raw materials often cannot be assigned unequivocally to specific types of adhesive. Because almost every polymer and resin and also many other substances in principle may be used for the production of adhesives, it is not possible to provide a complete list of every possible raw material. For this reason, only the most important are listed in the following.

Starch [*9005-25-8*] (→ Starch). Although their significance has decreased, the various types of starch, e.g., mainly potato and wheat starch in Europe, corn starch in North America, and tapioca in Latin America, Africa, and Asia/Pacific region, still represent an important group of raw materials in quantitative terms. Starches are used in native form, in degraded, hot- or cold-soluble form, and as solutions.

In addition, they are used in combination with casein solutions and synthetic resin emulsions. Whereas starch ethers and esters and also aldehyde starches are used to only a limited extent in the adhesives field, the thermal degradation products of starches, the water-soluble dextrins, are still important in quantitative terms as raw materials for adhesives. They are used on their own in aqueous form or as mixtures with synthetic resin emulsions.

Proteins. Whereas vegetable protein is of virtually no significance, milk protein is still important, although increasingly less so, for casein glues. The same applies to collagen from animal skins and bones for glue jellies and glutins.

Cellulose Ethers and Cellulose Esters. Cellulose ethers (→ Cellulose Ethers; → Cellulose Esters), primarily methyl cellulose, are used as aqueous solutions (wallpaper paste) and also as thickeners.

Nitrocellulose [*9004-70-0*] (→ Explosives) is used as a raw material for solvent adhesives (multipurpose adhesives, shoe adhesives), although in recent years it has been increasingly overtaken in importance by other polymers.

Natural Rubber [*9006-04-6*] (→ Rubber, 2. Natural). Pressure-sensitive adhesives, contact adhesives, rubber solutions, and other solvent adhesives are made from natural rubber (generally first-latex crepe). Solutions of regenerated rubber also have some significance. Before dissolution, natural rubber generally has to be degraded by mastication on rolls or in kneaders and solubilized. Soluble types are also available. Natural rubber latices (rubber latex) having solids content of from 35 to 70 % are widely used for special latex adhesives (envelope gumming and the like). Compared with synthetic rubber, natural rubber has better tack but is more sensitive to heat and oxidation, particularly in contact with nonferrous metals.

Synthetic Rubber (→ Rubber, 3. Synthetic). Many different types of synthetic rubber are suitable raw materials for adhesives and sealing compounds. Particularly significant are polychloroprene rubber, styrene – butadiene rubber (SBR), nitrile rubber, and polyisobutylene. Unless these rubbers are available as directly soluble types, they have to be degraded by mastication on rolls or in kneaders and solubilized before dissolution.

Standard contact adhesives and pressure-sensitive adhesives are made from SBR in solution. Styrene – butadiene rubber latices, in some cases containing carboxyl groups, are used for special emulsion-based adhesives. Thermoplastic elastomeric block copolymers of styrene with butadiene or isoprene are of increasing significance in contact adhesives and hot-melt adhesives (→ Thermoplastic Elastomers, Chap. 5.).

Polychloroprene rubbers are the principal raw material for high-quality contact adhesives. Grades with high degrees of crystallinity are used preferably. Polychloroprene latexes are raw materials for aqueous contact adhesives.

Nitrile rubber is used preferably for contact adhesives with improved plasticizer resistance. Polyisobutylene is used in pressure-sensitive ad-

hesives. Butyl rubber is sometimes added to pressure-sensitive and hot-melt adhesives, although it is mainly used in sealing compounds. Epoxy resins and reactive (meth)acrylate adhesives (reactive adhesives) are modified with polychloroprene, butyl, and nitrile rubber. Chlorinated rubber is added in small quantities to contact adhesives and also to rubber-to-metal bonding agents for improving the adhesion properties.

Polyethylene [*9002-88-4*] (→ Polyolefins). Low molecular mass polyethylene, vinyl-modified polyethylene and polyethylene waxes are used for hot-melt adhesives.

Chlorosulfonated polyethylene can used in reactive adhesives in combination with (meth)acrylate monomers and also in rubber-to-metal bonding agents.

Ethylene – vinyl acetate copolymers are the most important polymer raw materials for hot-melt adhesives. They contain 18 – 45 % vinyl acetate and have melt flow indices of from less than 1 to 2500. The quantitatively most important copolymers contain ca. 30 % vinyl acetate and having melt flow indices of 40 – 400. Ethylene – vinyl acetate copolymer emulsions containing ca. 20 % ethylene are used in emulsion-based adhesives.

Polypropylene [*9003-07-0*] (→ Polyolefins) and various copolymers are used in atactic form for standard hot-melt adhesives.

Poly(vinyl esters) [→ Poly(Vinyl Esters)] are one of the most important groups of raw materials for adhesives. Poly(vinyl acetates) are important in solvent adhesives. Synthetic resin emulsions, based on poly(vinyl esters) with a solids content of 50 – 70 % are the principal raw materials for emulsion-based adhesives.

Besides poly(vinyl acetate) emulsions, emulsions of vinyl acetate copolymers with ethylene, (meth)acrylates, vinyl chloride, maleic esters and vinyl laurate are of considerable importance as internally plasticized synthetic resin emulsions.

Poly(vinyl acetate) emulsions for adhesives contain preferably poly(vinyl alcohol) as a protective colloid. Spray-dried poly(vinyl acetate) emulsions, known as redispersion powders, are used in combination with cellulose ethers as binders in floor-leveling compositions and for increasing solids content in emulsion-based adhesives. Poly(vinyl acetates) are used as solid polymers for formulating solvent adhesives.

Poly(vinyl chloride) [*9002-86-2*] homopolymers [→ Poly(Vinyl Chloride)] are processed primarily into plastisol adhesives and special solvent adhesives. Chlorinated PVCs (ca. 65 % Cl) are more readily soluble and are used for certain solvent adhesives.

Copolymers of vinyl chloride are used both as solid resins, for example, in solvent adhesives (vinyl chloride – vinyl acetate copolymers), and as additives in plastisol adhesives, but especially as synthetic resin emulsions for heat-sealing adhesives. Important copolymers are those of vinyl chloride with vinyl acetate, acrylates, or maleates, as well as copolymers of vinylidene dichloride with acrylates or acrylonitrile.

Poly(vinyl alcohol) [*9002-89-5*] (→ Polyvinyl Compounds, Others) is used primarily as a protective colloid for poly(vinyl acetate) emulsions. Relatively small quantities are added to modify emulsion-based adhesives. Aqueous solutions of poly(vinyl alcohol), in some cases combined with fillers and emulsions, are used as paper glues and as labeling adhesives.

Poly(Vinyl Acetals) (→ Polyvinyl Compounds, Others). Poly(vinyl formal) and poly(vinyl butyral) are used in solution as primers, in combination with phenolic resins for specialty reactive adhesives, and as films for the manufacture of laminated glass.

Acrylate and Methacrylate Polymers (→ Polyacrylates; → Polymethacrylates). Poly(ethyl acrylate) and poly(butyl acrylate) solutions and emulsions are important raw materials for pressure-sensitive adhesives. Copolymers of various esters, which give films of tailor-made hardness and which may additionally contain functional groups (carboxyl, amide, amino, methylol, hydroxyl), are used for pressure-sensitive adhesives to improve the adhesion properties or to enable the adhesive layer to be cross-linked to a limited extent.

Methyl acrylates are used as comonomers for increasing the hardness of the adhesive layer.

Acrylate – styrene copolymers are used as emulsions for coating paper.

Solvent adhesives and reactive adhesives are made from homo- and copolymers of methacrylates, generally methyl and ethyl methacrylate and, occasionally, butyl methacrylate. Monomeric (meth)acrylates are also used in reactive adhesive systems (polymerization adhesives). Poly(ethylene glycol) dimethacrylates are the basis of anaerobically curing liquid resins (reactive adhesives). They also are added as adhesion promoters to plastisol adhesives. Acrylate – ethylene copolymers, in some cases with a small content of carboxyl groups, are used instead of ethylene – vinyl acetate copolymers as fusible polymers for special hot-melt adhesives. Salts of polyacrylate and acrylate – acrylic acid copolymers are used as thickeners for aqueous adhesive solutions and emulsion-based adhesives.

α-Cyanoacrylic esters (above all methyl, ethyl, butyl, but also allyl and methoxyethyl esters) are used for one-component reactive adhesives.

Poly(vinyl ethers) [→ Poly(Vinyl Ethers)] are used for specialty pressure-sensitive adhesives.

Polyvinylpyrrolidone [*9003-39-8*] (→ Polyvinyl Compounds, Others) is used in adhesive sticks and in aqueous pressure-sensitive adhesives.

Polystyrene [*9003-53-6*] (→ Polystyrene and Styrene Copolymers) is used as a solution for bonding polystyrene and other plastics.

Polyamides and Polyaminoamides (→ Polyamides) obtained by the condensation of dimerized fatty acids with aliphatic diamines are used in solid form as hot-melt adhesives with particularly pronounced adhesion properties. The low molecular mass condensates, some of which are still liquid and contain free amino groups (amine equivalent ca. 3000 – 12 000), are used widely as hardeners for epoxy resins.

Copolyamides based on C_{12} and C_{14} amino acids or lactams are preferably used as heat-sealing powders for textile applications.

Polyesters (→ Polyesters). Unsaturated polyesters dissolved in styrene or methacrylates are used as reactive adhesives. Hot-melt adhesives can be made from saturated and fusible polyesters based on aliphatic and/or aromatic carboxylic acids, in some cases by using dimerized fatty acids. High molecular mass amorphous polyesters and low molecular mass crystalline polyesters are important raw materials for moisture cross-linking polyurethane adhesives in solution or solvent-free systems.

Low molecular mass polyesters and polycaprolactones containing hydroxyl groups are important raw materials for polyurethane adhesives.

Polyurethanes (→ Polyurethanes), by virtue of their considerable variability, have become very valuable to the adhesives industry over recent decades. They generally show above-average adhesion and cohesion properties. Low molecular mass reaction products of hydroxyl compounds and polyisocyanates, which contain cross-linkable hydroxyl or isocyanate groups, are used for various reactive adhesives. The hydroxyl components are aliphatic and aromatic polyesters, polyethers, castor oil, and even simple polyalcohols.

High-polymer polyurethane rubbers with various crystallization properties are used for solvent adhesives, in some cases in combination with resins and other polymers, or for contact adhesives. In many cases, solutions of this type are also used for heat-reactivatable adhesive coats. By adding polyisocyanates, it is possible to improve both the adhesion properties and the bond strength at elevated temperature.

Polyisocyanates (→ Isocyanates, Organic). Whereas any standard, generally difunctional, polyisocyanate, but preferably toluene diisocyanate (TDI) and methylenediphenyl diisocyanate (MDI), may be used for the production of polyurethane resins, only polyisocyanates with low vapor pressures at room temperature, such as MDI and its homologues, the reaction product of trimethylol propane with TDI, and triphenylmethane-4,4′,4″-triisocyanate, are recommended as hardeners for adhesives for reasons of industrial hygiene.

Nonaromatic isocyanates such as isophorone diisocyanate (IPDI), hexamethylene diisocyanate prepolymers, and dicyclohexylmethane diisocyanate prepolymers have also gained some

importance. Guidelines for the use of isocyanates are given in [27].

Epoxy resins (→ Epoxy Resins) are used primarily in combination with hardeners (polyamines, polyaminoamides, dicyanodiamide, acid anhydrides) for cold-setting and hot-setting reactive adhesives. Liquid epoxy resins of the bisphenol A type with epoxy equivalents of 170 – 300 are used preferably; relatively high molecular mass solid resins are used only occasionally.

In quantitative terms, novolak epoxy resins (epoxy equivalent 120 – 200) and elasticized or otherwise modified bisphenol A (F) resins have relatively little significance.

Epoxy resins are also combined with phenolic resins and poly(vinyl acetate) resins and used as adhesion promoters, for example, in plastisol adhesives.

Phenolic Resins [*9003-35-4*] (→ Phenolic Resins). Curable phenol – formaldehyde resins of the resol type are of considerable importance as hot-setting reactive adhesives for bonding wood and metals. Suitable types are used also in combination with poly(vinyl acetals) and epoxy resins for special, in some cases filmlike, reactive adhesives for bonding metals.

Standard and modified phenolic resins, alkyl phenol resins, etherified phenolic resins, and phenol – terpene resins also are used as primers and resin components in other types of adhesives, for example, in contact cements, pressure-sensitive adhesives, rubber-to-metal bonding agents, and similar adhesive systems.

Resorcinol Resins [*24969-11-7*] (→ Resins, Synthetic). Resorcinol – formaldehyde resins and resorcinol – phenol – formaldehyde resins are used as cold-setting reactive adhesives for waterproof wood bonds and as binders between tire cord and rubber.

Urea Resins [*9011-05-6*] (→ Amino Resins). In quantitative terms, urea – formaldehyde resins are one of the most important groups of raw materials for adhesives. They are used in the form of aqueous solutions or spray-dried powders, generally containing acid hardeners, as reactive adhesives for bonding wood, particularly for the production of plywood and chipboard.

Modified urea resins are also important for other purposes, for example for labeling adhesives and as cross-linking components.

Melamine – formaldehyde resins [*9003-08-1*] (→ Amino Resins), like urea resins, are used primarily for bonding wood. Because they are not particularly stable in aqueous solution, melamine – formaldehyde resins are marketed primarily in powder form.

Nonreactive resins with a variety of compositions are of considerable importance in the formulation of adhesives. In some cases, they are used on their own in solvent adhesives, so-called resin adhesives, but generally in combinations with polymers, in which they perform various functions. Above all, they increase tack, improve adhesion, influence viscosity, fluidity, and sealability, and, in some cases, also act as plasticizers. The most important applications for nonreactive resins are in pressure-sensitive adhesives, contact adhesives, hot-melt adhesives, solvent adhesives, and emulsion-based adhesives. In this context, the term resin covers materials differing very widely in their composition:

Rosin and its derivatives (→ Resins, Natural)
Tall-oil rosins and their derivates (→ Resins, Natural)
Hydrocarbon resins (→ Resins, Synthetic)
Carbamic ester resins
Cyclohexanone resins (→ Resins, Synthetic).

Plasticizers. (→ Plasticizers) are used in adhesive formulations, above all for elastification of the polymer films in emulsion-based adhesives and also for increasing wet tack. They are used, e.g., in homopolymer emulsion-based adhesives. Phthalate plasticizers are the most widely used, diisobutyl phthalate being especially important for emulsion-based adhesives. In addition to phthalate and adipate plasticizers epoxy and phenol sulfonic amide plasticizers are used in PVC plastisols. Besides ester plasticizers, mineral oils and also chlorinated low molecular mass polyethylenes and low molecular mass hydrocarbon resins are used in rubber adhesives.

Other plasticizers, such as benzoates, citric esters, and glycerol triacetate are less important. In hot-melt adhesives, mineral oil and low molecular mass polyolefins are used.

Solvents, primarily for solvent adhesives, but sometimes also added to emulsions in small quantities as temporary plasticizers, are mainly petroleum, toluene, xylene, dichloromethane, trichloroethylene, trichloroethane, ethyl acetate, acetone, 2-butanone, methyl isobutyl ketone, and cyclohexanone. The use of solvents has been reduced significantly by the introduction of solvent-free adhesives (e.g., polyurethanes) in several market segments. Aromatic solvents, such as toluene and xylene, and chlorinated products like trichlorethane and dichloromethane have been nearly eliminated or are used in closed systems.

Fillers are added to adhesives primarily for establishing certain consistencies and occasionally for reducing cost. Preferred fillers are pyrogenic and precipitated silicas, chalks, and light and heavy spar. Fibers and metal powders are used in special cases [28].

Other Additives. Small quantities of standard preservatives, antioxidants, UV/light stabilizers, colored pigments, and defoaming agents are added to many adhesives.

5. Classification of Adhesives

Adhesives can be classified on the basis of chemical composition [29], setting mechanism [30], and adhesion mechanism as pressure-sensitive, adhesion, and diffusion adhesives [31]. Lucke [32] proposed a flexible classification in which each adhesive is characterized and classified according to various characteristic features, such as chemical basis, form of application, application temperature, thermal behavior, and uses. A classification such as this provides for very detailed coverage of the individual features of an adhesive and is a helpful guide for industrial users. However, it is extremely comprehensive and goes beyond the scope of this treatise. For this reason, a classification based on the setting mechanism is given here [30].

1. Setting without Chemical Reaction. The high molecular mass bonding substance is present prior to bonding.

1.1. Application without Volatile Solvents. The adhesive film is obtained by the action of heat.

Hot-melt adhesives, e.g., ethylene – vinyl acetate copolymers, polypropylene, polyamides, polyesters. Uses: paper, fiberboard, plastics, textiles, leather (assembly bonds).
Plastisol Adhesives. PVC or poly(methyl methacrylate) powder + plasticizer + adhesion promoter. Uses: metals (sheet-metal constructions), silicate-containing materials.

1.2. Application of Solutions, Solvent Escapes before Bonding. Adhesive layer is heated before or during bonding.

Heat-Sealing Adhesives and *High-Frequency Welding Auxiliaries,* e.g., vinyl polymers. Uses: paper, plastics, lamination of plastic films to metal foils (packaging, metal-foil lamination).
Contact Cements: elastomers (e.g., polychlorobutadiene) in conjunction with adhesive resins (e.g., alkylphenol or modified phenolic resins); bonding is obtained by contact under pressure between two almost dry adhesive layers. Uses: wood, plastics, rubber, metals.
Pressure-Sensitive Adhesives, e.g., natural and synthetic rubbers in conjunction with modified natural resins and/or synthetic resins; also polyacrylates, poly(vinyl ethers). Uses: nonspecific adhesion to virtually any surfaces, more particularly for the permanently tacky coating of tapes, films, and labels.

1.3. Application of Solutions, Solvent Evaporates during Bonding.

Solutions of polymeric, natural, and/or synthetic substances in organic solvents, e.g., vinyl polymers, natural rubber, synthetic rubbers of low polarity. Uses: paper, plastics, silicate-containing materials, wood.
Solutions of natural and synthetic high molecular mass substances in water, e.g., starch, dextrins, casein, cellulose ethers, water-soluble derivatives of poly(acrylic acid), poly(vinyl alcohol), poly(vinyl pyrrolidone) (adhesive sticks). Uses: paper, fiberboard.
Glutins (glues of animal origin). Uses: wood, paper, fiberboard, moistenable adhesive tapes.

1.4. Emulsions of Water-Insoluble Substances in Water that Escapes during Bonding.

Aqueous emulsions of polymeric compounds, e.g., homopolymers of vinyl acetate and vinyl propionate, vinyl acetate copolymers with ethylene or maleic esters; polyacrylic esters, styrene copolymers. Uses: paper, wood, also bonding to plastics.

2. Setting by Chemical Reaction (Reactive Adhesives). The high molecular mass bonding substance is formed during bonding.

2.1. Formation and Cross-linking of the Adhesive Film by Polymerization.

Two-pack polymerization adhesives: unsaturated polyesters with monomeric vinyl compounds, e.g., styrene or methyl methacrylate. No-mix adhesives and A/B acrylates, applied without premixing. Uses: metals, plastics, silicate-containing materials.
One-pack polymerization adhesives:

a) Cyanoacrylate adhesives setting under the influence of moisture or alkalinity. Uses: metals, plastics, silicate-containing materials, rubber, wood (high-strength spot bonds or small-area bonds).
b) Anaerobic adhesives. Special methacrylate adhesives. Uses: metals (threadlocking and bearing retention).

2.2. Formation and Cross-linking of the Adhesive film by Polyaddition.

Epoxy resin adhesives, polyepoxy compounds in combination with amines, polyamidoamines, or dicarboxylic acid anhydrides. Uses: metals, silicate-containing materials, plastics.
Reactive polyurethane adhesives: polyurethane prepolymers with terminal hydroxyl groups or terminal isocyanate groups. Uses: plastics, metals, silicate-containing materials.
Two-component silicone adhesives: setting induced by catalyst.

2.3. Formation and Cross-linking of the Bond by Polycondensation (elimination of low molecular mass cleavage products during setting).

Polyhydroxymethyl compounds: phenol – formaldehyde resins, also in combination with poly(vinyl formal) resins, nitrile rubber or epoxy resins (as adhesive film), urea – formaldehyde resins, melamine – formaldehyde resins, resorcinol – formaldehyde resins. Uses: wood (plywood manufacture), metals.
Silicone adhesives, one-pack, setting under the influence of atmospheric moisture. Uses: glass, metals, ceramics, plastics; some substrates need a priming coat.
MS polymers, siloxane-alkoxy-modified prepolymers of poly(propylene glycol), one-pack systems. Uses: Many surfaces; no primer necessary.
Polyurethane adhesives, one-pack, setting under the influence of atmospheric moisture. Uses: plastics, metals, silicate-containing materials.
Reactive polyurethane hot-melt adhesives, one-pack, setting under the influence of atmospheric moisture. Uses: bookbinding (high-quality perfect bindings), wood gluing, shoe manufacturing.
Polyimides and polybenzimidazoles. Uses: metals (for high thermal stressing).

2.4. Cross-linking of Polymeric Adhesive Components in the Bond. Rubber-to-metal bonding agents, e.g., halogenated polymers in conjunction with cross-linking agents; adhesion is obtained under vulcanization conditions (elevated temperature and pressure). Uses: natural and synthetic rubber to metals (structural elements for damping vibration).

2.5. Ultraviolet/Electron Beam (UV/EB) Curing Adhesives. Special acrylic acid esters (monomers or oligomers). Uses: for laminating and for pressure-sensitive products.

2.6. Conductive adhesives include electrically and thermally conductive materials. Most fillers that impart electrical conductivity also contribute to thermal conductivity, but thermally conductive adhesives that are electrically insulative are also available.

6. Individual Adhesive Systems

The same classification used in Chapter 5 is used here. Information on the uses of the adhesives discussed here can be found in Chapter 5.

6.1. Adhesives That Set Without a Chemical Reaction

6.1.1. Solvent-Free Adhesive Systems

Hot-melt adhesives are 100 % solids that, in the broadest sense, include all thermoplastic polymers. Polymers that are primarily used as hot-melt adhesives include ethylene – vinyl acetate copolymers (EVA), polyvinyl acetates (PVA), polyethylene (PE), amorphous polypropylene, block copolymers (thermoplastic elastomers), polyamides, and polyesters. The oldest hot-melt adhesive, which has been in use since early times, is sealing wax. In principle, glutins and glue jellies also may be regarded as hot-melt adhesives. However, modern hot-melt adhesives are primarily synthetic products. The simplest hot-melt adhesives are rosin – wax mixtures. But these products have limited strength and thermal stability.

In general, hot-melt adhesives are solid below 80 °C. Ideally, as the temperature is increased beyond this point, the material rapidly melts to a low-viscosity fluid that can be easily applied. Upon cooling, the adhesive sets rapidly. Because these adhesives are thermoplastics, the melting/resolidification process is repeatable. Typical application temperatures of hot-melt adhesives are 150 – 190 °C with melt viscosities in the range of 500 – 3000 mPa s.

Hot-melt adhesives do not undergo a chemical reaction because they simply cool from the melted state to form a solid film at the bond line. These adhesives are available in forms such as pellets, slabs, bars, slugs, and films that allow convenient handling by a variety of application equipment. Because hot-melt adhesives are applied in the molten state, melt viscosity is an important property. The limitations of the application equipment often influence the viscosity range that is selected for a hot-melt adhesive formulation.

Although hot-melt adhesives consist of 100 % solids, they are rarely 100 % polymers in composition. This is due to the limited adhesion of pure thermoplastics like EVA copolymers and their lack of melt properties such as tack and wettability. The components of a hot-melt adhesive can be roughly divided into two categories: polymers and diluents. Typically, diluents are waxes, plasticizers, tackifiers, stabilizers, extenders, and pigments. The functions of the diluents are:

Lowering the viscosity for easy application
Enhancing wettability
Enhancing adhesive strength
Increasing rigidity (extenders) or flexibility (plasticizers)

It is desirable to have a hot-melt adhesive with high strength. But this property is generally accompanied by a high melt viscosity. A low melt viscosity is desirable for application purposes. Therefore hot-melt adhesive formulations must include diluents that decrease the polymer melt viscosity and increase the overall adhesive strength.

Special dispensing equipment must be used to apply hot-melt adhesives. Typical application methods include the use of rollers, screw extruders, and squirting pumps or nozzle applicators.

The polymers are generally of high molecular mass and impart strength and high viscosity to an adhesive. Waxes such as paraffin wax can function as both diluents and antiblocking agents. In addition, waxes promote surface wetting. Similarly, plasticizers such as phthalates, mineral oils, and glycolates provide both surface wetting and adhesive flexibility. Typical tackifiers include rosin, modified rosin, terpenes, modified terpenes, hydrocarbons, and chlorinated hydrocarbons. These materials provide tack and flexibility while promoting surface wetting and adhesion. Stabilizers such as hindered phenols help to maintain adhesive melt viscosity while functioning as antioxidants. Extenders such as talc, clay, and barites lower the cost of hot-melt adhesives and simultaneously help control melt flow.

The following properties of hot-melt adhesives are important:

Melt viscosity is one of the most important properties of a hot-melt adhesive. In general, as the temperature of a polymer increases, its viscosity decreases. Therefore, in a hot-melt adhesive formulation, the melt temperature controls

the viscosity, which greatly influences the extent of surface wetting. The temperature of the melt and the application equipment should be maintained as constant as possible.

The *bond formation temperature* is the minimum temperature below which surface wetting is inadequate. A hot-melt adhesive is applied at a running temperature at which the viscosity is sufficient to wet surfaces properly. Running temperatures that are too high allow more time for surfaces to be wet properly. However, if low penetration is required and if the substrates are porous, this longer time may be detrimental and may result in a bond that contains insufficient adhesive. A running temperature that is too close to the bond-formation temperature may result in a too-rapid solidification of the adhesive bond. As a result, overall properties such as strength may not be optimized.

The *heat stability* of the adhesive is a very important property. Running temperatures that are greater than the adhesive degradation temperature result in charring and decreased overall properties. The addition of stabilizers to the adhesive formulation contributes to the stability of the material by hindering the acceleration of degradation due to the presence of oxygen.

The *tack* of the adhesive indicates the stickiness of the hot-melt as it changes from a liquid to a solid state. This property affects the ability of the adhesive to hold the substrates together.

The *open time* is the lapse of time between the application of the hot-melt to one substrate and the loss of its wetting ability on the second substrate due to solidification. It typically ranges from fractions of seconds to minutes to infinity (in pressure-sensitive hot-melt adhesives).

The *limitations* of hot-melt adhesives are restricted toughness at usable viscosities, low heat resistance, and poor creep resistance. All properties are affected by the polymer and diluents used in the formulation. The application conditions, including the amount of adhesive and the pressure applied to the bond line, also affect end-use properties. In the hot-melt adhesive-bonding operation, a minimum amount of pressure must be applied until the hot-melt becomes solid or sufficient tack develops to hold the substrates in place.

Manufacture. In the manufacturing of hot-melt adhesives, the components are melted in heated stirring vessels and subsequently formed in pelletizing or granulating machines. The melt is allowed to drop onto a cooling belt or to form a film on a cooling belt and subsequently cut. Another possibility is extrusion from an extruder followed by underwater granulation. For manufacturing hot-melt adhesives with higher viscosity and higher filler contents, it is preferable to use heatable kneaders or extruders followed by specialized processing units. Hot-melt sticks (slugs, rods) for application by handguns are produced by injection molding or by cutting hot-melt profiles.

Surface-tacky hot-melt adhesives are marketed in containers or in the form of blocks or cubes in readily removable packs (silicone-coated paper) [33] or in meltable polyethylene bags.

Hot-Melt Chemical Families. EVA copolymers are the cheapest hot-melt adhesives and are used in the greatest quantities. Typical properties of these adhesives include sufficient strength between ca. 30 and 50 °C, but limited upper service temperature of 60 – 80 °C, low hot-melt viscosity, and low creep resistance under load with time. Most EVA-based hot-melt adhesives are used to bond paper, fabrics, wood, and some thermoplastics.

PP polymers based on amorphous polypropylene have better properties than EVA hot-melt adhesives. In particular, higher heat resistance and better adhesion properties can be obtained.

Polyamides and thermoplastic polyesters are classified as high-performance hot-melt adhesives. These adhesives have greater strengths than EVA-based hot-melt adhesives and exhibit adequate bonding from approximately − 40 to 70 °C. Some formulations have upper service temperatures up to 185 °C for applications that do not involve loads. One disadvantage of the higher service temperatures is the higher hot-melt application temperature, which may require special equipment. Both polyamides and polyesters are sensitive to moisture absorption during application. This can result in hot-melt foaming, which leads to voids in the solidified adhesive and decreased strength. Nonetheless, polyamides exhibit good strength and flexibility. Polyesters are even stronger, but are more rigid and are usually highly crystalline. This results in a sharp melting temperature, which is desirable for high-speed bonding. Polyamide and polyester hot-melt adhesives are used to bond

plastics, glass, wood, leather, foam, fabric, rubbers and some metals, such as aluminum, copper, and brass.

Polybutene-based hot-melt adhesives are tough, partially crystalline, and their slow crystallization rates lead to long open times. Copolymers of butene result in softer and more flexible adhesives. In general, polybutene and its copolymers have low temperatures for recrystallization from the melt. This permits stress release in the adhesive bond, which may have been applied to cold surfaces. Polybutene and its olefinic copolymers exhibit good bonding to nonpolar surfaces but poor compatibility with polar substances. These hot-melt adhesives have been used on rubbery substrates and are available as pressure-sensitive adhesives.

Thermoplastic elastomers that are formulated into hot-melt adhesives include polyurethane and block terpolymers, such as styrene – butadiene – styrene; styrene – isoprene – styrene; and styrene – olefin – styrene, in which the olefin component is typically ethylene, propylene, and/or butylene. The saturation in the mid-segment of these terpolymers results in better UV and thermooxidative resistance than that of unsaturated butadiene and isoprene midsegments.

In general, thermoplastic elastomer hot-melt adhesives are not as strong as polyesters. However, they exhibit good flexibility, high elongation, toughness, and vibration resistance. Polyurethanes and block terpolymers are used as hot-melt pressure-sensitive adhesives in tapes and labels and for nonwoven applications.

Pressure-sensitive hot-melt adhesives are surface-tacky and can be used by the application of pressure alone. These adhesives have infinite open times and are used at room temperature. Typically, pressure-sensitive hot-melt adhesives are supplied in form of blocks or cubes in silicone coated packaging units or preferably in polyethylene bags, which after melting form part of the adhesive.

Foamable hot-melt adhesives have been commercially available since 1981. Nitrogen or carbon dioxide is introduced into the hot-melt adhesive and results in a 20 – 70 % increase in adhesive volume. Foaming increases hot-melt spreading and open time. This method is usually used with polyethylene hot-melt adhesives that are applied to selected metal, plastic, paper, porous, and heat-sensitive substrates.

Low-melt adhesives are hot-melt adhesives with an application temperature in the range of 100 – 120 °C instead of 160 – 190 °C. They are used for bonding heat-sensitive materials.

Plastisol adhesives are solvent-free adhesives that require temperatures of 120 – 200 °C for setting. They consist essentially of a dispersion of finely divided poly(vinyl chloride) or polymethacrylate [34] in plasticizers and low molecular mass, heat-reactive substances that act as adhesion promoters, for example, epoxy resins, poly(ethylene glycol) dimethacrylates, phenolic resins; in some cases these are even used in conjunction with corresponding hardeners. Standard heat stabilizers for poly(vinyl chloride) are also added to prevent decomposition of the poly(vinyl chloride) and evolution of HCl during hardening or in the event of subsequent exposure to heat. Depending on the end use, varying amounts of fillers, pigments, or thixotropizing agents may be added to modify the color and fixing behavior. At a certain setting or hardening temperature, the poly(vinyl chloride)/polymethacrylate plasticizer mixture becomes a dispersion gel and also adheres to the substrate through reaction of the adhesion promoter. The various adhesion promoter systems require different activation temperatures, usually in the range of 120 – 200 °C [34].

Production and Storage. Because of their relatively high viscosities, these pasty to highly viscous compositions must be produced in kneader-type stirring vessels capable of applying considerable forces. It is important to ensure that stirring and kneading do not generate excessive temperatures, which can result in gelation of the product. For the same reason, the products must be stored under cool conditions (below 30 °C).

6.1.2. Adhesive Solutions from Which the Solvents Escape before Bonding

This group includes heat-sealing adhesives and high-frequency (HF) sensitive heat-seal coats; these are coating adhesives that are heat-activated during bonding. Contact adhesives and

pressure-sensitive adhesives bond by the same principle but without the action of heat.

Heat-sealing adhesives are applied to the materials to be sealed in the form of solutions, emulsions, or, preferably, in melt or powder form. The solvent-free layer is intended to be nontacky and only to melt and to wet the adherent under the action of heat during sealing. Solidification takes place after cooling. In many cases, sealing is carried out on a coating-to-coating basis.

The choice of raw materials for sealing coatings is very wide and is influenced by the sealing temperature and the sealing behavior of the materials used, by the requirements the joint has to satisfy, and by the adhesion of the sealing layers to the substrates. In many cases, copolymers of vinyl chloride or vinylidene chloride are used in solution, although they are also used in emulsion in conjunction with resins and other polymers. In addition, copolymers of vinyl acetate and polymethacrylates, polyurethanes, and polyesters are also used. Ethylene – vinyl acetate copolymers are used preferably for heat-sealing coatings applied as melts. Heat-sealing powders also are used occasionally; they can be based on fine polyamide or polyethylene powders and also on vinyl acetate – vinyl chloride copolymers.

High-frequency-sensitive heat seal coats are a special type of heat-sealing adhesive [35]. They are also applied in the form of a solution or emulsion to the surface of a substrate and dried. However, welding to the partner substrate is not obtained by the application of heat through the substrate; instead the sealing temperature is generated by high frequency within the adhesive layer itself. Hence, the adhesive layer must have a high dielectric loss factor.

High-frequency sealing auxiliaries generally contain vinyl chloride copolymers in addition to proportions of other polymers, such as polyacrylates, vinyl acetate copolymers, plasticizers, and resins. High-frequency heatable coatings have solids contents of from 30 % (solutions) to 50 % (emulsions). Their activation temperature is in the range of 120 – 150 °C. High-frequency sealing powders consist predominantly of finely divided polyamides.

Contact cements must be applied to both substrate surfaces to be joined. The adhesive layers are joined only when the solvents have almost completely evaporated. A brief, but as high a contact pressure as possible is required for bonding. The strength of the adhesive joint is relatively high immediately after contact bonding and may amount to 50 % of the final strength. In principle, the contact adhesion effect may be obtained with natural rubber solutions, as known, for example, from the repair of bicycle inner tubes with rubber solution. However, the actual contact cements are solutions of synthetic rubbers with resins or solutions of high molecular mass polyurethane elastomers. The rubber components are mainly polychloroprene, nitrile – butadiene, and styrene – butadiene rubbers, and the resins used are primarily phenolic resins, rosins, and hydrocarbon resins. In the case of polychloroprene adhesives, metal oxides are added as stabilizers. In some cases, the rubber starting materials are high molecular mass rubbers that must be masticated on rolls or in internal mixers before dissolution, but mainly directly soluble rubbers are used today. The rubber, resin, and additives are dissolved in the appropriate solvents or solvent mixtures in closed stirring vessels to form the end product. The solid contents of the products varies from 20 to 30 %; the more sprayable types have lower solids contents.

The highest strengths are obtained with a uniform, thin coating of adhesive coupled with a high contact pressure. It is important to allow for adequate evaporation of the solvents and to observe the open time of the contact adhesive.

Contact cements based on nitrile rubber and polyurethane are more resistant to oils and plasticizers than polychloroprene adhesives. To improve adhesion and to increase thermal stability, contact adhesives may be applied together with isocyanate hardeners. Today solvent-free contact adhesives based on aqueous polychloroprene latexes are also available.

Trade Names. In Germany: Pattex, UHU Greenit; in Japan: Cemedine, Bond G, Sunstar; in the USA: Pliobond, Fastbond, Elmer's.

Pressure-sensitive adhesives are permanently tacky substances that adhere spontaneously to the surfaces of most materials with only light pressure [36]. Their adhesiveness is

relatively nonspecific, although the individual products show different adhesion values on different substrates. Pressure-sensitive adhesives are used mostly for coating supports, for example, paper and film tapes, adhesive labels, or self-adhesive decorative sheeting. The adhesives are applied to the supports as solutions, dispersions, or melts. After the adhesive has set, the pressure-sensitive adhesive is present as a thin film on the support and, until it is used, is covered by suitable antiadhesively finished materials, for example silicone paper or siliconized polyethylene film. In some cases, the pressure-sensitive adhesive is also applied to the masking material, and the film of pressure-sensitive adhesive formed is transferred to the actual carrier by the reverse process. The dry application weight varies between 4 and 40 g/m^2, depending on the end use and the roughness of the carrier or substrate to be bonded.

In general, bonds formed with pressure-sensitive adhesives show relatively high resistance to brief and rapid loads. Under permanent load or stress, however, they tend to creep, particularly at elevated temperature. The property spectrum of pressure-sensitive adhesives is characterized by adhesiveness and resistance to heat, aging, and plasticizers.

The raw materials used for pressure-sensitive adhesives are natural and synthetic rubbers in conjunction with modified rosins, phenol – formaldehyde resins, or hydrocarbon resins. In addition to rubber, polyacrylates, polymethacrylates, poly(vinyl ethers), and polyisobutenes also are used frequently, again mostly in combination with resins. Silicone resins are used for special applications.

Pressure-sensitive adhesive dispersions are based primarily on special acrylic ester copolymers, again generally in combination with resins. In addition to suitable resins, two polymer bases are used primarily for hot-melt pressure-sensitive adhesives, namely, ethylene – vinyl – acetate copolymers and styrene – butadiene or styrene – isoprene block copolymers, which also are known as thermoplastic rubbers.

It is said that a pressure-sensitive adhesive always must be composed of a high-polymer base resin, which determines cohesion and specific adhesion, and of tackifying resins (tackifiers). In some systems, the tackifier may be replaced by low molecular mass fractions of the base polymer. To increase cohesion, the base resin in some systems is cross-linked or, in the case of rubber-based pressure-sensitive adhesives, vulcanized after application.

6.1.3. Adhesive Solutions from Which the Solvents Evaporate during Bonding

Solutions of Polymeric Substances and Resins in Organic Solvents. A distinction is be drawn between adhesives that set by evaporation of the solvent and form an adhesive joint by adhesion of the dissolved polymer to the substrate surfaces, and adhesives for plastics, the solvent of which dissolves and swells the plastics surfaces and joins them by means of migration processes. This allows bonding of plastics that are otherwise difficult to join. The polymer solutes in solution adhesives act primarily as thickeners for establishing certain flow properties and retaining the solvent for the duration of the dissolution process. These solid components also may perform a limited gap-filling function.

Adhesion Adhesives. The best known solvent-containing adhesives are the *multipurpose adhesives*. They can not join every type of substrate, but can bond a wide range of substrates with different results. They contain as binders high molecular mass compounds that adhere to many different surfaces, preferably nitrocellulose and poly(vinyl acetate). The solvent mixtures consist of esters and ketones and, in some cases, also contain alcohols. The composition of the solvent is determined by the polymers used, by the required fluidity of the adhesive, and by the required open time or setting time. The solvents may dissolve certain plastics.

Solutions of natural and synthetic rubber, polyurethane rubber, ethylene – vinyl acetate copolymers, polyacrylates, and other polymers with additions of resins and plasticizers are also used. These polymers can be used in solvents or as dispersions in water.

Trade Names.In Germany: UHU Alleskleber, Pritt Alleskleber; in Japan: Saivinol, Cevien-A; in the USA: Elmer's School Glue, Wilhold Glu-Bond.

Solvent Adhesives. In solvent adhesives for bonding plastics, the composition of the solvent

is particularly important with regard to dissolution and swelling of the plastics to be bonded. Synthetic resins from the same class or from a related class are used for thickening.

The PVC adhesives have been used since the 1930s for bonding PVC resins. They are solutions of chlorinated poly(vinyl chloride) in acetone, cyclohexanone, THF, or mixtures thereof. The THF-containing adhesives are solutions of PVC in mixtures of THF, 2-butanone, and cyclohexanone. Organic thickeners are used to obtain pseudoplastic solutions that can be applied in sufficiently thick layers. By virtue of their stronger dissolving and swelling effect, THF adhesives can bridge certain gaps.

Pure solvents, such as aromatic hydrocarbons, halogenated hydrocarbons, solvent mixtures, or even solutions of polystyrene in these solvents are used for bonding polystyrene, ABS, and other styrene copolymers.

Trade Names. Solution adhesives for rigid PVC: Tangit, Dytex (Germany); Hamatide, S-dine (Japan); Bostik, Datey (USA).

Solutions of Natural and Synthetic Polymers in Water.

Aqueous Starch- and Dextrin-Based Adhesives. The starch- and dextrin-based adhesives reached their zenith between 1920 and 1935. Since then, they have been increasingly superseded by synthetic resin-based adhesives, and they are now important only in certain applications. However, they are still used in considerable quantities for applications such as labeling adhesives, paper-sack adhesives, and envelope gums.

The raw materials used for the various types of starch- and dextrin-based adhesives are chiefly potato starch and cornstarch and, to a far lesser extent, tapioca starch and wheat starch. Potato starch is preferred for liquid glues, at least in Europe, where it is widely available.

Native *starch* is not soluble in water. To obtain soluble starches, the starch granule must be gelatinized by the prolonged heating of an aqueous starch suspension above the gelatinization temperature (e.g., 62.5 °C for potato and cornstarch, 67.5 °C for wheat starch) or by treatment with alkali at lower temperature. The gelatinization temperature and also the gelatinization rate can be varied by adding electrolytes.

To obtain certain solution viscosities and structures, the starch molecule must be degraded before and after gelatinization. A starch suspension is exposed before gelatinization to the action of acids, primarily nitric acid, or oxidizing agents, such as hydrogen peroxide, at elevated temperature. The greatest degradation is carried out in the case of dextrination. Because of the different degrees of degradation, the various gelatinization processes, and additives that influence hydration, the adhesives obtained differ considerably in their rheology, adhesive strength, and application properties; they are marketed as ready-to-use adhesives and as cold-water- or warm-water-soluble powdered adhesives. All aqueous starch- and dextrin-based adhesives must be protected against biological degradation by additions of preservatives [37].

Dextrin-based adhesives are available as powdered dextrins, which are dissolved in water before application, and ready-to-use aqueous dextrin adhesives with a dextrin content of 50 – 70 % and viscosities of 3×10^4 to 3×10^7 mPa s.

Dextrins are produced by the thermal and acid-hydrolytic degradation of native starch, generally cornstarch and potato starch. Dextrin-based adhesives are produced by dissolving powdered dextrins or dextrin mixtures of differing degrees of degradation in water. Mixtures of 60 – 70 % dextrin and 30 – 40 % water are heated in glass-lined vessels to 80 – 100°C until a homogeneous solution is formed. Commercial dextrin-based adhesives differ in the type of dextrins or dextrin mixtures used, the solids content, and in the additives present, such as hygroscopic salts ($CaCl_2$, $MgCl_2$), borax, glycerol, sugar or sugar syrup, and similar substances).

The viscosity of dextrin-based adhesives can be reduced by vigorous stirring. However, the viscosity of dextrin-based adhesives generally undergoes a marked increase after production, so that they have to be left to mature. In most cases, dextrin-based adhesives are marketed only after the maturing process is complete.

Mixed Glues. Starches and dextrins also are used in combination with other raw materials in adhesives. For example, the resistance to water of starch-based adhesives can be improved by the addition of melamine – formaldehyde or urea – formaldehyde resins. Mixtures of starch-

based adhesives or dextrin-based adhesives with synthetic resin dispersions are also used.

Casein glues are also still important. Casein is obtained by precipitation from milk protein. The dried powder is mixed with water prior to application and hardens by loss of water at room temperature, with some chemical conversion of protein to more insoluble calcium derivatives. This adhesive is unsuitable for outdoor use but is more resistant to temperature changes and moisture than other water-base adhesives. Casein adhesives tolerate dry heat up to 70 °C and have good resistance to organic solvents. Although they are susceptible to biodegradation, chlorinated phenols can be used to inhibit this behavior. Typical applications include packaging (paper labels for glass), woodworking, and fabrication of interior-grade plywood.

Other Aqueous Adhesive Solutions. Besides starches and dextrins, *cellulose ethers,* primarily methyl cellulose and carboxymethyl cellulose, and in some cases also *starch ethers,* are important as wallpaper pastes and poster glues. The products are generally marketed in the form of powders that are dissolved in water by the user. Aqueous solutions of *poly(vinyl alcohol)* can be used to a limited extent. In most cases, fillers are added to these solutions.

Poly(vinyl pyrrolidone) has acquired significance as a binder in adhesive sticks. In addition to the polymer, these sticks consist primarily of a soap/water gel as builder. After application, the water evaporates, leaving the solid behind as bonding agent [39].

Aqueous Glutins (Animal Glues). The significance of animal glues or glutins has steadily diminished in the last decades. Like gelatin, glutines are obtained by acidic or alkaline hydrolysis of the collagen present in animal bones, hides, etc. (→ Gelatin). The degradation product, which forms colloidal solution in water, is called glutin. Particularly pure glues are known as gelatin glues. In some cases, gelatin waste is also made up into glues.

The glutin solutions that accumulate in the processing of bones and hides are concentrated to a solids content of 30 – 55 %. They solidify on cooling to form firm, cuttable jellies. The slabs or blocks are further reduced in size, dried to a solids content of 85 %, and marketed in various forms. Hide glues are stronger than bone glues and often exceed the strength of wood. These adhesives are primarily used to bond wood, leather, paper, and textiles. Use is limited to interior applications. The setting of glutins is determined primarily by solidification of the gelatin or glutin/water mix on cooling and secondarily by evaporation of the water.

The reversible uptake and release of water by glutins has advantages and disadvantages. The possibility of activating layers of glue jellies by moistening is utilized, for example, in the production of moistenable gum tapes [40].

6.1.4. Aqueous Emulsions of Polymeric Compounds

Emulsion-based adhesives are adhesives that contain aqueous synthetic resin dispersions or emulsions or rubber latices as their principal raw material or active binder [41]. They are milky white, odorless liquids with solids contents of 40 – 60 %. In quantitative terms, emulsion-based adhesives are one of the most important groups of adhesives. They set by the release of water and the formation of a film from the emulsified or dispersed resin or rubber droplets.

The number of resin emulsions and rubber latexes suitable for use as raw materials for adhesives is very large. Emulsions of homopolymers and copolymers of vinyl acetate are the most important. The comonomers for vinyl acetate include maleic esters, acrylates, ethylene and vinyl chloride, unsaturated carboxylic acids, and vinyl esters of relatively long-chain fatty acids, such as vinyl laurate. Apart from these products, polyacrylate homopolymers and copolymers and also styrene copolymers are particularly important in adhesives [42].

Additions of plasticizers, solvents, and resins improve the specific adhesion of the synthetic resin emulsions, and also are capable of lowering the film-forming temperature and increasing the tackiness of the wet adhesive. Poly(vinyl alcohol), cellulose ethers, and other hydrocolloid additives prolong the open time. Poly(vinyl alcohol) also can improve wet tack. Certain applications require fillers, which may be used in such large quantities that pasty mortars and cements are formed.

The elasticity of the set films can be increased by plasticizers and by copolymerization. Redispersion powders, that is, spray-dried synthetic

resin emulsions, are added to synthetic resin emulsions to increase their solids content and their setting rate.

Synthetic resin emulsions containing reactive groups also have appeared on the market. The reactive groups provide for subsequent cross-linking, making it possible, for example, to increase the resistance of the joints to water. Mixed adhesives consisting of synthetic resin emulsions and starch- or dextrin-based adhesives have advantages in certain fields and are generally cheaper.

Latex adhesives are based on natural rubber or on various types of synthetic rubber. Occasionally, mixtures of natural rubber and synthetic resin latices are also used. In general, resins or solvents also are used in the production of latex adhesives.

In the production of latex adhesives, overvigorous stirring can affect the rheological properties of the adhesives, which are often pseudoplastic and differ in their mechanical stability. Characteristic properties of emulsion-based adhesives include viscosity and flow properties, the setting and breaking behavior of the emulsion, the wet tack or green strength of the film, the minimum film-forming temperature, storage behavior at low temperatures (freezing temperature), and specific adhesion to various materials. Films of emulsion-based adhesives are tested only occasionally for tensile strength and elasticity. The redispersibility of the set adhesive films is important with regard to the cleaning of machine components and recycling of paper.

6.2. Adhesives Setting by Chemical Reaction

Before setting, reactive adhesives consist predominantly of reactive low molecular mass monomers and/or oligomers that, during curing, are converted by chemical reactions into high molecular mass, often three-dimensionally cross-linked polymers. Reactive adhesives can be divided into polymerization, polyaddition, and polycondensation adhesives. Vulcanizing reactive adhesives are a special group.

Reactive adhesives are marketed as one-pack, two-pack, and no-mix formulations. Two-pack adhesives must be completely mixed in the correct ratio before use. The mixtures have a limited pot life. One-pack adhesives are easier to handle during application. They are hardened by heat, by the catalytic action of the substrate, or by atmospheric moisture.

Cold-setting reactive adhesives harden within a few hours to several days at room temperature or slightly elevated temperature. An exception are cyanoacrylate adhesives, which cure on several substrates within seconds or minutes, as do UV/EB curable adhesives. Warm-setting adhesives generally require temperatures in the range 80 – 100 °C, and hot-setting adhesives 100 – 250 °C. Adhesive joints of particularly high quality are obtained mainly with warm- and hot-setting systems. In many cases, warm setting leads to higher bond strengths, even in the case of systems that normally harden at room temperature. However, even certain cold-setting adhesives produce outstanding bond strengths under favorable bonding conditions.

To avoid mixing errors in the case of two-pack adhesives, no-mix adhesives are available. In this case, one of the surfaces to be bonded is pretreated with the adhesive resin, the other with the adhesive primer, and the bond is formed instantly when the two surfaces are brought together.

6.2.1. Adhesives Setting by Polymerization

Polymerization adhesives harden through radical or ionic polymerization of the monomers; at the same time, graft polymerization or cross-linking of the dissolved, still polymerizable polymers also may occur.

Two-Component Polymerization Adhesives. The best known types are polymerization adhesives based on solutions of *unsaturated polyesters* in styrene or (meth)acrylates. Peroxides are added as hardeners to the resin component; amines or heavy-metal salts are used as accelerators.

More important and with better properties are the cold-setting, two-component *acrylate adhesives,* which contain methacrylates or acrylates, sometimes mixed with styrene and methacrylic acid as monomer and, in addition, various polymers. The polymers used are primarily synthetic rubbers, such as polychloroprene, styrene – butadiene rubber, butyl rub-

ber, polystyrene, polymethacrylates, and acrylate graft polymers of these polymers. Amines are used as accelerators, and benzoyl peroxide in the form of plasticizer pastes or a powder mixture with fillers is preferred as hardener [43].
Trade Names.In Germany: Agomet, Pattex Stabilit Express; in Japan: Hard-Lock, Sumikitt; in the USA: Versilok.

One-Component Polymerization Adhesives.

Cyanoacrylate Adhesives. Methyl, ethyl, butyl, and methoxyethyl esters of cyanoacrylic acid are used for cyanoacrylate adhesives [44]; soluble polymers and plasticizers are incorporated to regulate viscosity and for elastification. Cyanoacrylate adhesives rapidly polymerize by an ionic reaction mechanism initiated simply by weak bases to form high molecular mass, but largely uncross-linked polymers. In most cases, atmospheric moisture or the film of moisture on the substrate is sufficient to initiate polymerization, because the adhesives are applied in very thin layers. However, this sensitivity to atmospheric moisture means that the adhesives must be stored in tightly sealed form, usually in polyethylene bottles. Cyanoacrylates are used for bonding small items of nearly all substrates. In case of polyethylene or polypropylene special primers are available. Setting is complete with rubbers in seconds, with aluminum in less than one minute.

Cyanoacrylate adhesives are also used in surgery [45]. They enable parts of the body to be joined together and, therefore, must be used carefully.
Trade Names.In Germany: Sicomet, Loctite, Pattex Blitzkleber; in Japan: Aron Alpha, Alteco, Cianobond; in the USA: Superbonder, Permabond, Super Glue, Krazy Glue and Attak.

Anaerobic adhesives Anaerobic adhesives are mixtures of acrylic esters which remain liquid when exposed to air but harden when confined between metal surfaces. These mixtures can be used for a large number of industrial purposes such as locking threaded fasteners, sealing threaded pipe connections, retaining cylindrical machine components, sealing flange joints, bonding structural components, sealing porous metal castings, welds and powdered metal parts and many other applications which are still being found more than forty years after the initial invention [134]. Several reviews have been published which describe anaerobic adhesives and their applications [135–137].

All anaerobic-curing adhesives consist of a monomer, an initiator, one or more accelerators, and stabilizers. The properties of the cured and uncured adhesives can be modified to control viscosity, color, or fluorescence, reduce strength, increase toughness or heat resistance, provide lubrication and reduce settling of solid fillers. In some applications anaerobic sealants cure more rapidly if the surface is treated with chemicals which catalyze their polymerization.

A number of papers discuss the *reaction mechanisms* of anaerobic adhesive cure [138–142]. The polymerization mechanism of anaerobic adhesives is similar to that of other radical initiation systems except for the special way in which the inhibiting effect of oxygen is used to delay the polymerization and in the chemical activation which occurs at the metal surface.

Initiation:

$$\mathrm{I} \longrightarrow \mathrm{I}^{\bullet}$$

$$\mathrm{I}^{\bullet} + \mathrm{M}^{\bullet}$$

Inhibition:

$$\mathrm{M}^{\bullet} + \mathrm{O_2MOO}^{\bullet}$$

Propagation:

$$\mathrm{M} + \mathrm{M}^{\bullet} \longrightarrow \mathrm{M}^{\bullet}$$

Termination:

$$\mathrm{M}^{\bullet} + \mathrm{M}^{\bullet} \longrightarrow \mathrm{M_2}$$

$$\mathrm{M}^{\bullet} + \mathrm{I}^{\bullet} \longrightarrow \mathrm{MI}$$

The reaction rate of oxygen with free radicals is very high, and the resulting peroxy radical is a relatively poor initiator. When the supply of oxygen is used up within a thin bond line the propagation step can provide rapid development of adhesive strength.

An important factor in the initiation of anaerobic adhesive cure is the redox reaction between a hydroperoxide and transition metals with adjacent oxidation states [138].

$$\mathrm{Fe^{2+}} + \mathrm{ROOH} \longrightarrow \mathrm{Fe^{3+}} + \mathrm{RO}^{\bullet} + \mathrm{OH^{-}}$$

$$Fe^{3+} + ROOH \longrightarrow Fe^{2+} + ROO^{\bullet} + H^{+}$$

Other transition metals react similarly, and copper is particularly active.

The use of saccharin and *N,N*-dimethyl-*p*-toluidine results in a substantial acceleration of the initiating reaction. Although each of these components is an accelerator by itself the combination has a strong synergistic effect. It has been suggested that a charge-transfer complex is formed by these materials [139]. It has been suggested that one of the functions of saccharin in anaerobic curing is to dissolve metal ions from the surface that then catalyze the decomposition of CHP [142]. The role of the bonding surfaces and the effect of different types of accelerators account for most of the literature on the cure mechanism of anaerobic adhesives.

The first patents on anaerobic adhesives mentioned only the polyglycol dimethacrylates as *monomers*, mainly tetraethyleneglycol dimethacrylate [143], [144]. The use of acrylic or methacrylic acids to improve adhesion to smooth surfaces was mentioned in [145]. A series of polyurethane polyacrylates were prepared by reaction of toluene diisocyanate, other isocyanates, and isocyanate-terminated oligomers with hydroxyalkyl methacrylates [146]. These monomers could be tailored to provide the strength and toughness for some structural adhesive applications. The incorporation of hard and soft segments into the polyurethane backbones provided significant improvements in toughness, cure-through-gap, and cryogenic strength properties [147].

The use of monomethacrylates in anaerobic formulations was disclosed in a patent assigned to Loctite. Specifically mentioned were hydroxyethyl, hydroxypropyl, cyclohexyl, tetrahydrofurfuryl, dimethylaminoethyl, and glycidyl methacrylates and cyanoethyl acrylate [148].

Methacrylate esters containing residual carboxylic acid groups were prepared by the reaction of hydroxyethylmethacrylate with phthalic anhydride, pyromellitic dianhydride, and benzophenone tetracarboxylic acid dianhydride. The residual acid provided improved adhesion [149], [150]. The reaction product of hydroxyalkylmethacrylates with maleic anhydride also produced monomers with residual acid as well as additional curable unsaturation [151].

Three Bond Company used trimethylolpropane trimethacrylate [152] and ethoxylated bis-phenol A dimethacrylate [153] in anaerobic formulations. These monomers have some advantages in providing improved heat resistance.

At Henkel dicyclopentadienyl methacrylate was used in anaerobic formulations with high strength [154]. Rohm & Haas disclosed the use of dicyclopentenyloxyethyl acrylate and methacrylate in anaerobic formulations [155]. These monomers provide good cure strength on metal parts which have not been degreased and also have lower odor and volatility than the corresponding dicyclopentadienyl esters.

Silicone methacrylates have been formulated into anaerobic adhesives by Dow Corning [156], Toshiba Silicones [157], and Loctite [158], [159].

The most commonly used *initiator* for anaerobic adhesives is cumene hydroperoxide. Many other hydroperoxides have been disclosed such as *tert*-butyl hydroperoxide, *p*-menthane hydroperoxide, diisopropylbenzene hydroperoxide, pinene hydroperoxide and methyl ethyl ketone hydroperoxide [160].

Storage-stable anaerobic formulations can be prepared without hydroperoxide if the methacrylate resin is aerated in the presence of an amide and a tertiary amine [161].

The first *accelerator* used in an anaerobic adhesive was tri-*n*-butylamine [162]. Saccharin was also found to be an effective accelerator [163] and the combination of saccharin and *N,N*-dimethyl-*p*-toluidine was particularly effective if properly stabilized [164].

Many patents have been issued on various accelerators and combinations thereof. 1-Acetyl-2-phenylhydrazine [165], [166], benzenesulfonyl hydrazide [167], dibenzenesulfonamide [168], and other similar compounds have been disclosed.

The use of saccharin is of particular interest, and a number of compounds have been prepared which have a similar chemical structure and reactivity. The reaction of sulfuryldiisocyanate with acetic acid gives a disulfonamide which is an effective accelerator [169]. Similar reactions of *p*-toluenesulfonyl isocyanate and chlorosulfonyl isocyanate can be used to prepare many different compounds which are active accelerators [170], [171]. These methods allow the

preparation of accelerators with improved solubility.

The monomers used in anaerobic adhesives and sealants generally contain at least one free radical *stabilizer* such as hydroquinone or *p*-methoxyphenol. Benzoquinone, naphthoquinone, and similar compounds provide improved shelf stability without retarding the anaerobic cure [172].

The use of a soluble metal-chelating agent such as tetrasodium ethylenediamine tetraacetate effectively stabilizes an anaerobic formulation against small amounts of metal contamination [173]. The wide variety of applications of anaerobic adhesives and sealants is made possible by the modifications which make the viscosity appropriate to the application. An application which requires penetration into close fitting parts should have very low viscosity while a product used with large, loose fitting parts should have a high viscosity. Polymethacrylates, cellulose esters, butadiene – styrene copolymers, acrylonitrile – butadiene – styrene copolymers, poly(vinyl chloride), copolymers of vinyl chloride and vinyl acetate, poly(vinyl acetate), cellulose ethers, polyesters, polyurethanes, and other thermoplastic resins have been used to control the flow characteristics of anaerobic sealants [174].

The flow characteristics of anaerobic formulations can also be controlled by the addition of fumed silica and other solid additives which can impart thixotropic properties [175].

Many anaerobic adhesives and sealants may be required to develop a relatively low strength so that the components can be disassembled for repair or replacement. Many liquid plasticizers have been used for this purpose [176], but the use of a low molecular mass polyester is advantageous [177].

The "toughness" properties of anaerobic adhesives can be enhanced by the addition of a reactive elastomer [178]. The heat resistance of anaerobic adhesives and sealants can be enhanced by the addition of a bis-maleimide [179]. These maleimide additives appear to be relatively unreactive during the initial anaerobic cure. As the adhesive is exposed to high temperatures, the methacrylate backbone degrades and the methacrylates can then copolymerize with the maleimides to form a more heat resistant matrix [180].

The addition of dyes to anaerobic adhesives and sealants assists in identification and inspection of the products. Automated inspection procedures are made possible with dyes that fluoresce under ultraviolet light. Titanium dioxide pigments can make the sealants opaque and more visible.

Solid fillers are added to some anaerobic adhesives and sealants for various purposes. Mica, talc and other mineral fillers can help to provide an "instant seal" capability to anaerobic pipe sealants. The sensitivity of the anaerobic cure system to metal contamination requires that these fillers be chosen very carefully.

Powdered graphite, polytetrafluoroethylene, and polyethylene can function as lubricants in pipe sealants and threadlocking compounds. This lubrication can prevent galling in close-fitting pipe threads [181]. Lubricating additives in thread-locking sealants can provide control of the clamping force exerted by a fastener at a given tightening torque.

The cure speed and adhesion of an anaerobic sealant can be increased by treatment of the surface with a solution of a *primer* or *activator*. Early anaerobic thread lockers were strongly affected by part cleanliness, and degreasing the parts with a chlorinated solvent improved performance dramatically. The condensation product of an aldehyde and a primary or secondary amine, a sulfur-containing radical accelerator, or a compound of an oxidizable transition metal were some of the materials used to activate the anaerobic cure [182–184]. Due to the ozone-depleting potential of chlorinated solvents, acetone, alcohols, or hydrocarbon solvents are generally used at present.

Modified acrylics, also referred to as second-generation acrylics or no-mix adhesives, are composed of a modified acrylic adhesive and a surface activator. Typical modified acrylics are based on cross-linked polymethyl methacrylate grafted to vinyl-terminated nitrile rubber. Carboxyl-terminated rubbers have also been used.

Unlike epoxies, which cure by an ionic polymerization mechanism, modified acrylics cure by free-radical addition. Therefore, careful proportioning of components is not required. In two-component systems, no mixing is required because the adhesive is applied to one substrate,

the activator to the other, and the substrates are joined. Handling strength is rapidly achieved with this fast-curing system.

Modified acrylics have good peel, impact, and tensile lap-shear strengths. High bond strengths are obtained with metals and plastics even if surfaces are oily or improperly cleaned. The cured adhesive exhibits little shrinkage. Resistance to high humidity is good, particularly when bonding plastic substrates. The limitations of modified acrylic adhesives include low high-temperature strength, flammability of the primer, which is an amine (Schiff base) or a peroxide in a solvent, and the odor of the uncured adhesive.

Trade Names. In Germany: Agomet, Multi-Bond; in Japan: Diabond SGA, Cemedine SGA; in the USA: Versilok.

A/B acrylates are a new class of acrylate adhesives. They are two-component adhesives that cure rapidly after application. They avoid using a solvent-based primer as in modified acrylics. The acrylates used are mainly acrylated polyurethane oligomers, compounded with catalyst in one component and accelerator in the other. The two components can be applied 1/1 without mixing as beads side by side. Mixing is performed by coating the materials to be bonded or by a static-mixer applicator. Curing starts immediately after mixing. Handling strength is attained rapidly, and final curing is complete after several hours. An advantage over modified acrylics is the lesser odor due to the use of oligomers instead of monomers.

Trade Names. In Germany: Omnifit A/B; in the USA: Loctite.

6.2.2. Adhesives Setting by Polyaddition

Epoxy Adhesives. Epoxies [47], [48] are among the most widely used structural adhesives. These chemically reactive systems include two-component systems that cure at room temperature or elevated temperature and one-component systems, which usually require heat for curing.

Epoxy thermoset adhesives, available in many formulations, can be used to join most materials. These adhesives have good strength, do not emit volatile substances during curing, and have low shrinkage. However, peel strength and flexibility are low, and epoxies are brittle.

A typical two-component system consists of a resin and a hardener, which are packaged separately. In a one-component system, the resin and hardener are packaged together. Other possible additives include accelerators, reactive diluents, plasticizers, resin modifiers, and fillers.

The most common epoxy resin is based on the diglycidyl ether of bisphenol A. Epoxy resins are sometimes esterified with fatty acids or modified with polyurethane intermediate chains for elastification.

The hardeners used for *hot-setting formulations,* i.e., for hardening temperatures above 100°C, are preferably dicarboxylic acid anhydrides, dicyandiamide, and certain aromatic amines. The hardening temperatures, which are normally in the range 150 – 200°C, can be lowered by adding accelerants [49].

The hardeners for *cold-setting systems* include aliphatic and cycloaliphatic amines and polyamines, adducts of polyamines and epoxy resins, phenol – amine combinations, and condensates of polyamines and dimerized fatty acids (polyaminoamides). Whereas amine hardeners must be used in a stoichiometric ratio to the reactive epoxy groups, polyaminoamides may be overdosed to a certain extent and thus used to elasticize the adhesive resin.

An exothermic reaction occurs during the curing of epoxies. This reaction can be minimized by lowering the temperature of the mixed components in two-component systems, by limiting the batch size, and by using shallow mixing containers.

Epoxies are brittle, especially if cured with an anhydride. Therefore, thermoplastics and rubbery modifiers are often added to decrease the brittleness.

Nylon epoxy, which first became available in 1960, has an approximate maximum service temperature of 180 °C, compared to 80 °C for unmodified epoxies. The main advantage of nylon epoxies is increased flexibility and much higher peel strength, compared to unmodified epoxies. Also this very tough material has excellent tensile lap-shear strength. Fatigue and impact resistance are also good. Limitations include poor peel strength at low temperatures and poor creep resistance. Perhaps the most serious limitation is extremely poor moisture resistance

in both the uncured and cured material. Nylon epoxies are not as durable as elastomer epoxies or thermoplastic-modified epoxies. A typical application of nylon epoxies is in laminates.

Elastomer epoxies generally contain nitrile rubber as the elastomeric component. This system is also referred to as a modified or toughened epoxy. One of the applications of widest use is in films and tapes. Elastomer epoxies cure at low pressures and low temperatures over a short time interval. This is achieved by adding a catalyst to the adhesive formulation. Bond strengths of elastomer epoxies are lower than those of nylon epoxies. However, the major advantage of elastomer epoxies is their sub-zero peel strengths, which do not decrease as fast as those of nylon epoxies. In addition, the moisture resistance of elastomer epoxies is better than that of nylon epoxies but not as good as that of vinyl – phenolics or nitrile – phenolics. Limitations to the use of elastomer epoxies include poor water immersion resistance and poor properties when exposed to marine conditions.

In addition to liquid and pastelike epoxy resin adhesives, solid powdered products are also available commercially. In addition, epoxy resins are used in the form of adhesive films for certain applications. The most important are nylon epoxy resin films consisting of mixtures of relatively high molecular mass polyepoxides and polyamides, and epoxy resin – phenolic resin combinations.

Trade Names. In Germany: Araldite, Metallon, Pattex Kraft-Mix, UHU-plus, Scotch weld, Terokal; in Japan: Sho-bond, KBK, Bond E, Sanyu Resin; in the USA: Scotch Weld, Resiweld, Ross Epoxy Glue, Ten-set Epoxy and Duro E-pox-e Glue.

Reactive Polyurethane Adhesives (for the raw materials → Polyurethanes) date back to the late 1930s and acquired their present economic significance over the past decades [50–52]. They are distinguished by good adhesion to various substrates and, compared with other reactive adhesives, by high elasticity, even at low temperatures. Polyurethane adhesives are marketed both as solvent-free and as solvent-based adhesives.

The generic term polyurethane adhesives covers both adhesives that already contain polyurethane compounds or compounds with a urethane bond and also reactive adhesives in which urethane groups are formed only during the hardening process.

Chemically reactive polyurethanes include both one- and two-component systems. One-component systems are usually based on a polyether polyol treated with a polyisocyanate to give an isocyanate-terminated polymer. A one-component system cures when exposed to moisture at room temperature. One-component polyurethane hot-melt adhesives are also cured by moisture after application. Two-component systems result from the reaction of low molecular mass polyols and isocyanates or from isocyanate-terminated prepolymers with either polyols or polyamines. Two-component systems cure at room and/or elevated temperatures.

One-component heat-curable urethanes are also available. In these formulations, free isocyanate groups are typically blocked by the addition of phenol. The prepolymer is then blended with the polyglycol curing agent and packaged. The mixture is stable until heated to elevated temperatures, whereupon the phenol is released and the isocyanate groups are regenerated. A rapid cure occurs when these groups come into contact with the polyglycol.

Polyurethanes bond to most surfaces. They also have outstanding tensile lap-shear strength at lower temperatures. In fact, polyurethanes have better low-temperature strength than any other adhesive, even epoxy – nylons. Good flexibility, abrasion resistance, and toughness are other advantages of polyurethanes. Limitations include sensitivity to moisture in both uncured and cured adhesives, the toxicity of isocyanates, and poor tensile lap-shear strength at higher temperature. A major advantage, and also the reason for the wide range of applications of polyurethane adhesives, lies in their versatility in regard to raw materials, composition, and curing.

Normally, reactive polyurethane adhesives contain high molecular mass, still reactive polyurethane prepolymers with terminal hydroxyl or terminal isocyanate groups. Prepolymers with terminal hydroxyl groups can be hardened by the addition of polyisocyanates. Depending on the functionality of the prepolymers and polyisocyanate hardeners, curing may involve both cross-linking and linear enlargement of the molecule. High molecular mass polyurethane elastomers contain urethane

groups that can still react with isocyanates and are thus cross-linked (contact cements).

Prepolymers with terminal isocyanate groups can react with and are hardened both with amino or hydroxyl compounds and with water. Hardening with water is preferred for one-pack systems, for which both atmospheric moisture and the film of water on the substrates act as hardeners for the prepolymer. Cross-linking with polyamines is particularly fast compared with curing by polyols.

One-pack polyurethane adhesives can also be manufactured by protecting the isocyanate groups of prepolymers with, for example, phenols or oximes, which are split off by the action of heat during bonding. Protected polyisocyanates can also be added to reactive polyurethane adhesives as latent hardeners. Tertiary amines or organotin compounds can be added to accelerate isocyanate reactions.

Polyurethane adhesives should be stored in tightly sealed containers, because shelf life and adhesive quality can be affected adversely by the uptake of water.

Trade Names. In Germany: Liofol, Macroplast; in Japan: Diabond, Bostik; in the USA: Chemlok.

6.2.3. Adhesives Setting by Polycondensation

Polyhydroxymethyl Compounds. Hydroxymethyl compounds that release water during condensation are used primarily for polycondensation adhesives. Accordingly, the high-quality bonding of impermeable substrates requires relatively high pressures to compensate for the water vapor pressure developed during hot setting. Polycondensation adhesives are used both in pure form and as solutions in water or organic solvents. Hardening can be initiated by the application of heat or by the addition of hardeners.

Polycondensation adhesives include phenolic and resorcinol resins and also urea – and melamine – formaldehyde resins (→ Phenolic Resins; → Amino Resins). Adhesives of particularly high quality are obtained by combining phenolic resins with poly(vinyl formal) resins, nitrile rubber, or epoxy resins. Combinations such as these are often marketed as adhesive film.

Trade Names. In Germany: Redux, Tegofilm, Kaurit, Pressal.

Phenolics or phenol – formaldehyde structural adhesives are chemically reactive systems that cure to form thermosets. In one-component systems, meltable powders (resols) are used as binders for particle board or as alloys (including nitrile – phenolics, vinyl – phenolics, and epoxy – phenolics), which are used in the structural bonding of metals. In two-component systems, the resin and catalyst are mixed and then heated to initiate curing. Both systems cure by a condensation reaction that produces a byproduct.

In general, phenolics are low-cost adhesives with good strength and resistance to biodegradation, hot water, and weathering. Elevated-temperature resistance is also good. Limitations include low impact strength and high shrinkage stresses, which lead to brittleness. Shelf life is limited, the adhesives are dark colored, and they can be corrosive.

Phenolics dominate the wood adhesives market, especially for plywood. The structural adhesive bonding of metals, particularly with phenolic alloys, is another application.

Nitrile – phenolic alloys are composed of nitrile rubber and phenolic with additives. These systems are available in liquid or film form. The advantages include a maximum service temperature of 140°C, low cost, high bond strength, and excellent resistance to water, oil, biodegradation, and salt. Disadvantages include poor to moderately poor low-temperature resistance and high-pressure, high-temperature curing. Typical applications include the bonding of metals, plastics, rubber, wood, glass, and ceramics. This structural adhesive is used in automobile brakeshoes and clutch disks and in aircraft applications.

Vinyl – phenolics are alloys composed of polyvinyl formal (PVF) – phenolics or polyvinyl butyral (PVB) – phenolics. They are available as liquids and films. In general, vinyl – phenolics have a maximum service temperature of 80°C and are equal to phenolic – nitriles in strength. These adhesives are better than epoxies in sandwich structures that require high strength.

PVF – phenolics have good resistance to fatigue, weathering, fungi, salt, humidity, water, and oil. Creep resistance is good in some formulations, but is poor in others above 90°C. These adhesives are used in metal-honeycomb and wood – metal applications.

PVB – phenolics also have good resistance to weathering, fungi, salt, humidity, water, and oil, and creep and fatigue resistance are even better than those of PVF – phenolics. These adhesives are used to bond metal or reinforced plastic facings to paper honeycomb, cork to rubber, and steel to rubber.

Epoxy – phenolic adhesives are also available as liquids or films. They are among the best adhesives for long-term use at 150 – 250 °C. In general, epoxy – phenolics are relatively expensive. They have fairly good shear and tensile strengths over a wide temperature range, but peel strength is poor. Impact resistance is also poor, whereas resistance to weathering, aging, aromatic fuels, glycols, hydrocarbon solvents, and water is good. Typical applications include the bonding of metals, glass, ceramics, phenolics, and honeycomb sandwich structures in aircraft applications.

Silicone Adhesives (for the raw materials → Silicones). Cold-cross-linking one-pack silicone adhesives also harden by a polycondensation mechanism. They are silanols whose OH groups have reacted with acetic acid or amines. Treatment of these compounds with water leads to the elimination of acetic acid or amines and generates the reactive silanols, which cross-link with elimination of water. These products are particularly important as sealing compounds in the building industry.

Usually silicones are available as both one- and two-component systems that cure to thermoset solids. A one-component room-temperature-vulcanizing silicone cures at room temperature upon exposure to atmospheric moisture. Curing is either acidic or nonacidic in the presence of moisture. Adhesives that have an acidic cure have greater unprimed adhesion and a longer shelf life. However, the corrosion of metals by the acid is a potential problem. Thin films of approximately 0.6 mm cure within 90 min., whereas 15 mm films of require ca. 7 d to achieve full cure.

Two-component silicones do not require moisture to cure. During the addition polymerization of silicones, curing is achieved by catalytic action. Pot life, setting time, and cure time are dependent on the catalyst concentration. A system with 5 % catalyst will typically have a 3 h pot life, a 22 h setting time, and a 7 d cure time at room temperature. Increasing the temperature accelerates curing. Addition-polymerized silicones exhibit little shrinkage upon curing and have good high-temperature resistance. In the condensation polymerization of two-component silicones, byproducts are released. These systems are less likely to be inhibited and can be used on a greater variety of substrates. However, reversion of polymerization is a potential problem.

In general, silicone adhesives have good peel strength over a service temperature range of – 60 to 250 °C. Some have limited service to 370°C. Flexibility and impact resistance are good, as are resistance to moisture, hot water, oxidation, and weathering. Typical lap-shear strengths are low in metal-to-metal bonds, with values ranging between 1 and 3.5 MPa. The cost of these adhesives is high.

Silicone adhesives are useful in bonding metals, glass, paper, plastics, and rubbers, including silicone, butyl rubber, and fluoroelastomers.

MS Polymers. A relatively new class of adhesives are the two-component MS polymer adhesives, known as moisture-cross-linkable sealants up to know. Due to their excellent elastic properties they are used for elastic bonding. Chemically they are based on silane-modified prepolymers such as poly(propylene glycol). The end groups of these so-called MS polymers are silanealkoxyl groups which are hydrolyzed by water and then cross-link. In comparison to silicone adhesives, they adhere to all kinds of surfaces without any primer and are paintable in the freshly cured state.

Polyimides and Polybenzimidazoles [53]. The highly temperature resistant polyaromatic adhesive resins of the polyimide and polybenzimidazole type are applied as precondensates in the form of solutions or films and are condensed to completion at 230 – 250°C under a relatively high pressure of 8 – 10 bar. The precondensates remain stable for only a few hours

at room temperature and have to be stored at −18 °C.

These structural adhesives with high-temperature resistance are based on synthetic organics with aromatic (benzene) and/or heterocyclic rings in the main structure. These chemical groups often include imidazoles and substituted imidazoles. These prepolymers have open-ring structures that close upon application of heat. The condensation reaction leads to a highly cross-linked structure. The adhesives are available as liquids and films. High-temperature adhesives, including polyimides and polybenzimidazoles, are expensive materials that are difficult to handle and require long curing times during which volatile substances are released. Polyimides are superior with regard to long-term strength retention at elevated temperatures. At 260 °C in air, polyimides have higher bond strength than epoxy – phenolics. Polybenzimidazoles are stable in air for short-term exposures up to 290 °C. Both polyimides and polybenzimidazoles are moisture-sensitive. Applications of high-temperature adhesives are primarily in the aircraft and aerospace industries for bonding metals.

6.2.4. Vulcanizing Adhesives

Adhesives for joining unvulcanized elastomers to metals or plastics under vulcanization conditions are called rubber-to-metal bonding agents. Mixtures of film-forming components, cross-linking agents, and stabilizers dissolved in organic solvents are used as bonding agents. The solids content varies from about 15 to 25 % according to type. The film-forming components used are chiefly halogenated polymers, whereas the cross-linking agents are, for example, nitroso compounds, isocyanates, and oximes in combination with an oxidizing agent [54]. In many cases, primers are applied additionally to the metal surface to improve resistance to corrosion. Trade Names. In Germany: Chemosil; in Japan: Metalok; in the USA: Chemlok.

6.2.5. Ultraviolet/Electron Beam (UV/EB) Curing Adhesives

Most UV/EB adhesives are based on an addition polymerization curing mechanism. They consist of acrylic esters of various types or combinations of acrylates with aliphatic or aromatic epoxy resins, urethanes, polyesters, or polyethers. Although the epoxy-based systems have higher tensile strengths, their elongations are less than those of the urethane-based systems. In addition, the urethane-based systems have better abrasion resistance. UV/EB adhesives that undergo cationic polymerization are based on epoxies with reactive diluents and cyclic monomers. The main advantage of UV/EB-curable adhesives is rapid curing at room temperature, so they can be used to bond heat-sensitive substrates, such as poly(vinyl chloride). In addition, the rapid cure often eliminates the need to fix parts and greatly increases production rates.

UV/EB-cured adhesives have been used to replace solvent-base adhesives because of the increasing cost of properly recovering and disposing of solvents. Most of these adhesives are single-component materials that require no mixing and produce little waste.

The cross-linked nature of UV/EB-cured adhesives results in good chemical, heat, and abrasion resistance; toughness; dimensional stability; and adhesion to many substrates. Unlike thermal curing, EB or UV curing requires pure raw material grades. The use of dual-curing systems allows opaque substrates to be cured.

The mechanical properties of UV-curable structural adhesives are dependent on polymer molecular mass and cross-linking density. These factors are related to the prepolymer, degree of stiffness or flexibility, and functionality. The overall adhesive strength is affected by:

Adequate UV transmission through the bond line
Adhesive thickness
UV intensity
Postcuring (by heat or exclusion of oxygen, as in anaerobics)

The main components of UV/EB-cured adhesives are reactive oligomers which contribute adhesion, toughness, and flexibility to the overall properties of UV/EB adhesives. Typical reactive oligomers include acrylated epoxy resins and aromatic urethanes.

Monomeric diluents are low molecular mass monofunctional molecules that reduce the viscosity of liquid oligomers. Some, such as

methacrylates, increase the toughness and adhesion. Various types of acrylates are used as reactive monomers.

Cross-linking monomers such as 1,3-butylene glycol dimethacrylate, tripropylene glycol diacrylate, and pentaerythritol tetracrylate are also used in UV/EB adhesive formulations.

Free-radical initiators trigger the cross-linking reaction. In EB-cured adhesives, the electrons act as free-radical initiators for addition polymerization. Therefore, no chemical initiator additives are needed. In UV-cured adhesives, photoinitiators, which release free radicals when exposed to UV radiation, are required to initiate addition polymerization. The most recent UV- and EB-curing systems involve cationic polymerization mechanisms.

Typical UV-curable adhesive applications include the electronics, automotive, medical, optics, and packaging industries, as well as tapes and labels. EB-curable adhesives are used in magnetic tapes and floppy disks, where magnetic particles are bonded to films, as well as in packaging, tapes, and labels.

Laminating adhesives have the largest share of the UV/EB-curable adhesives market. Adhesives are applied and then cured in-line. The lack of solvent in these adhesives eliminates the drying step required when using solvent-based adhesives. The high degree of cross-linking in UV/EB-cured laminates gives high bond strength, good heat resistance, and good chemical resistance. Substrates that are typically laminated include: film to paper, foil, fabric, glass, film, or wood; paper to foil, wood, or paper; wood to wood; and glass to glass or metal.

The pressure-sensitive sector of the UV/EB-curable adhesives market is not nearly as large as that of the laminating-adhesives segment. Because slight changes in exposure time greatly affect peel strength and tack, the formulation of these adhesives is critical. Three approaches are used to make pressure-sensitive adhesives. The first is based on a UV-curable system employing conventional tackifiers blended with UV-reactive moieties. The process must be closely controlled to attain repeatable tack and peel strength. The second approach is based on an EB-curable system that is actually a hot-melt adhesive. EB-cross-linkable thermoplastic rubbers are usually used in these adhesives and result in hot-melt pressure-sensitive adhesives with better heat resistance than conventional elastomeric hot-melt adhesives. The third approach involves the development of inherently tacky oligomers for pressure-sensitive adhesives.

There are several limitations to the use of UV/EB-cured adhesives. EB equipment is expensive. UV equipment is less expensive, but the materials themselves are usually more costly because of the need for photoinitiators. To cure adhesives properly, one substrate must be transparent to UV radiation. However, the necessity of having a transparent substrate has been removed by the introduction of dual-curing adhesives. These adhesives are quickly set by a UV cure and are more fully cured by a second mechanism involving the introduction of heat or moisture or the elimination of oxygen (anaerobics). In EB-curable adhesive, the depth of EB penetration is limited by the density of the material, rather than its opacity.

The cure time of UV adhesives is usually less than 60 s and depends on:

Bond-line joint thickness: As the thickness increases, UV radiation loses its ability to penetrate totally, necessitating a second cure.

Type of substrate: A transparent substrate such as glass with a small gap may take as little as 5 s to cure. Opaque and darker substrates require longer curing times.

Light intensity: The more intense the UV light, the faster the cure.

The curing time of EB adhesives is comparable to that of UV adhesives. In general, EB radiation allows adhesive curing to be achieved at greater depths than is possible with UV radiation. Electrons can pass through substrates that are opaque to UV light. In addition, the area of exposure and the depth of penetration can be controlled by means of the EB conditions.

6.2.6. Conductive Adhesives

Conductive adhesives include both electrically and thermally conductive materials. Most adhesive fillers that result in electrical conductivity in a material also contribute to its thermal conductivity. However, thermally conductive adhesives that are electrically insulative are also available.

The majority of applications involve the use of silver, either in flake or powder form. This

filler is preferred to gold because of its lower cost and its lower volume resistivity (that is, higher electrical conductivity). The best silver-filled epoxies have a volume resistivity of 0.001 Ω cm. With silver-filled adhesives, migration of silver to the surface under conditions of high humidity and direct current can occur. Neither gold- nor silver-coated copper fillers in various adhesives have this migration problem. Epoxies with up to 85 wt % silver filler are available, but adhesives with lower filler loadings generally have better strengths.

Other fillers that provide electrical conductivity include copper and aluminum, although oxide formation on the surfaces of these fillers can occur. This results in lower conductivity because of decreased particle-to-particle contact.

Conductive epoxy resins and polyimides are used as die-attach adhesives. The chloride ion contents of polyimides are inherently lower than those of epoxies. However, these adhesives are more expensive, have lower bond strength, and are more difficult to cure. Epoxies with low contents of ionic impurities, including chloride anions and sodium and potassium cations, have been available since 1981. These materials are fast curing and have excellent high-temperature strength and a glass transition temperature of up to 200 °C.

Oxide fillers are electrically nonconductive but are used to provide thermal conductivity. Alumina, the most commonly used filler, is fairly inexpensive. It can be added in high concentrations to epoxies and silicones without significantly increasing the viscosity of the uncured material. Minimum bond line thicknesses are desirable for thermally conductive adhesives because heat flow is proportional to the ratio of thermal conductivity to bond thickness. Alumina-filled epoxies contain up to 75 wt % filler and have thermal conductivities ranging from 1.38 to 1.73 $W\,m^{-1}\,K^{-1}$.

Other thermally conductive fillers include beryllium oxide, which is expensive and toxic, and boron nitride, which has a loading limitation of ca. 40 wt % in epoxies. Other inorganic oxides, including silica, are also used to provide thermal conductivity.

The chemical families that are used most often to provide electrical and/or thermal conductivity include epoxies, polyurethanes, silicones, and polyimides. Epoxies are the most widely used.

7. Bonding Techniques

Cleaning and Pretreatment of the Surfaces to be Joined. To insure good adhesion of the adhesives, the surfaces to be joined must be cleaned before the adhesive is applied. Layers of grease, oil, and lubricant are removed by means of solvents or aqueous degreasing baths. Loose dirt and oxide layers can be removed by brushing. In many cases, the surfaces to be joined are rubbed down with emery paper or sandblasted to remove firmly anchored layers that would interfere with the bonding process or to enlarge the surface by roughening. Pretreatment processes are used additionally to increase the affinity for bonding or (adsorption) activity of the surface and even to impart an affinity for bonding to certain plastics. In general, acidic pickling baths and often combined acidic and oxidizing pickling baths are used for metals, generating defined oxide layers. Alkaline pickling baths are used relatively infrequently. In plastics that are difficult to bond, the surface is modified by chemical pretreatment processes that increase the surface tension of the plastics and, hence, also their wettability and bondability [55]. The so-called corona treatment, i.e, electrical discharge in the presence of air, is used primarily for pretreating plastics films and, in some cases, also metal foils.

In addition to the cleaning and pretreatment of the surfaces to be joined, primers are applied before the actual adhesive in individual cases, their function being to improve the adhesion of the adhesives and/or favorably to influence the resistance to aging and corrosion of the bond.

Adhesive Application. Water-based adhesives and pigmented solvent-based types should be stirred thoroughly before application to remove possible inhomogeneity. For two-component or multipackage adhesives exact dosage and homogenous mixing of the components is essential. The method of application of the adhesive determines the uniformity of the bond line, the thickness of the adhesive layer, and therefore the quality and economy of the bonding process. The application method itself

depends on the size and nature of the surface, the rheology of the adhesive, the required coating thickness, the number of components to be bonded and the speed of the process.

Manual application of the adhesives with toothed spatulas, blades, casting knives, or brushes is the simplest but least uniform method of application. Pasty adhesives can be applied from cartridges which are squeezed by hand or mechanical devices. This method is also used for moisture-curing polyurethane hot-melt adhesives with heated cartridges.

Low-viscosity adhesives are distributed over large areas by spray guns in the same way as paints (Fig. 1). The spraying process may involve the usual atomization with air or can be airless in the case of solvent-based adhesives.

Rollers are a versatile application method and range from simple glue rollers fed from a reservoir to highly sophisticated systems with several rolls, suitable for hot-melt, solvent-based, water-based, and solvent-free reactive adhesives (Figs. 2, 3, 4, 5, 6). The coating thickness is regulated by the distance between the rollers, the friction between them (different rotational speeds) and/or by blades. By this means, it is possible to apply from 0.5 g/m^2 up to $>$ 20 g/m^2 in a very precise operation.

Figure 6. Reserve roll coating system (System Pagendarm)
a) Adhesive

Gravure rollers are used together with doctor blades for a constant coating weight over the width in a narrow range of thickness. Unless the entire surface must be coated with adhesive, slim rollers or so-called wheel applicators are used. If the adhesive is only applied at intervals or with interruptions, segment rollers or wheels, interrupted rollers, toothed wheels, profile rollers, rollers with moving segments, or plungers are used. In addition, blade coating and airbrush coating are used. Hot-melt adhesives must be melted prior to application by rollers. The adhesive is usually transferred from the rolls to the substrates by direct coating in the machine direction. In some cases, reverse-roll coating (Fig. 6) has advantages, especially for low-viscosity adhesives.

Curtain coaters are used for applying adhesives over wide areas by passing the web below the nozzle of the tank (Fig. 7). Highly viscous hot-melt adhesives and thermoplastic polymers are applied from wide-slot nozzles to form a weblike film on the substrate.

Figure 7. Curtain coater
a) Adhesive; b) Flowing adhesive "curtain"; c) Casting slot

Typically, hot-melt adhesives for folder packaging are liquefied in melting tanks or drum melters and then pumped through heated hoses to the application nozzle. The piston pumps or gear pumps generate sufficiently high pressures to allow contactless application or spraying.

The porous coat system (Nordson) allows the application of discrete, random, and open patterns of hot-melt adhesive to substrates such as films, papers, fabrics, and nonwovens. With the control coat system, hot melt adhesives are applied continuously or intermittently by air-controlled nozzles without contact to the substrate. This technique is used as well for reactive hot-melt adhesives such as moisture-curing polyurethane hot-melt adhesives.

For temperature-sensitive substrates and prolonged open times, gases are incorporated in the melt under pressure. As a result, a hot-melt foam is formed during application [56].

The application units of solvent-free laminating machines consist of three or four rollers with differential speeds to lower the coating weight to 1.5 g/m^2, enabling machine speeds from 250 up to 500 m/min.

Relatively simple handguns (Fig. 8) are used for the workshop or do-it-yourself application of hot-melt adhesives.

Metering and mixing units (Fig. 9) of various constructions (gear pumps, piston pumps, static mixers) are used for the application of two-component adhesives and provide precise dosing and mixing even at elevated temperatures (70 °C).

Anaerobic reactive adhesives and cyanoacrylate adhesives are applied by means of special metering units that dispense small predetermined quantities at the required time intervals.

Joining, Fixing, Drying, and Hardening. After applying the adhesive to one or both surfaces, the substrates have to be fitted together within the open time and fixed until the bond is sufficiently firm. The pressure that has to be applied for bonding is determined only to a minor extent by the adhesive and largely depends on the geometry, nature, and deformability of the substrates and by its recovery forces.

The pressure for joining and fixing to give whole-surface contact can be very high, particularly in the case of large-area bonds, although the adhesive itself does not require such high pressures, apart from contact and hot-setting condensation adhesives. The necessary pressure is usually applied by pressure rollers, laminating rollers, or braces and presses.

The setting time and hence the fixing time can be shortened by heating. Warm-setting adhesives require certain minimum temperatures and times for curing. The energy required may be supplied by recirculating air ovens, drying tunnels in laminating machines and lacquering ovens, by radiant heaters, and by contact heating in heated presses or laminating rollers. Inductive heating of metal-to-metal bonds and high-frequency infrared heating of aqueous adhesives are also used occasionally. Within the last years UV-curing adhesives have been introduced, while electron-beam-curing adhesives are still in the development stage.

Polycondensation adhesives must be subjected during hot hardening to an external pressure that is higher than the vapor pressure of the cleavage products formed during condensation. Accordingly, these adhesives are applied in heated presses or by using pressure bags in heated ovens. The vacuum/pressure process in heated autoclaves is preferably used for uneven, three-dimensional surfaces [57].

A special case of bonding is the heat-sealing of previously applied heat-seal adhesives. Such coatings are converted by heat into a tacky state and bonded by the application of pressure. Thermal activation is carried out by heated sealing bars or plates, hot air, and sometimes by IR radiation.

High-frequency welding is used for special applications, in which cases the necessary heat is generated by the interaction of high-frequency radiation with the dipole moment of the pre-applied heat-seal adhesive itself.

8. Testing of Adhesives

The testing of adhesives comprises two aspects:

1) The adhesive as an individual compound
2) The performance in the actual adhesive joint that is formed between substrates

Generally the following adhesive properties are determined:

Solids content
Rheological properties
Shelf life or storage temperature range
Mechanical properties: tensile strength, modulus, Shore hardness, and elongation to break
Glass transition temperature
Softening point
Flammability and flash point
Health and environmental classification

More important, however, is the performance of the adhesive in an actual joint. Standard test specimens are bonded under standard conditions and subjected to destructive tests. The load values of these tests give information on the adhesive strength between two bonded substrates. Standard destructive test methods are:

Tensile test (EN 26922)
Flatwise tensile shear test (EN 1465)
Peel test (EN 1464/ISO 4578 and EN ISO 28510-1,2)

Figure 10. The most important kinds of strain for bonded joints
A) Tensile strain; B) Shear strain; C) Peel strain.

Standard destructive tests are, above all, tensile, shear, and peel tests on specially made, strip-form test specimens (Fig. 10). In general, short-overlap test strips are used for tensile shear tests and flat-bonded test strips for peel tests.

Bending and impact tests occasionally are carried out on these or similar test specimen geometries. Apart from the adhesive itself, the material of the test specimen, surface treatment of the specimen before bonding (sandblasting, pickling, priming), dimensions, overlap surface area, the test speed, the test temperature, and the direction in which the force is applied, all affect the outcome of these tests. Accordingly, the nature and dimensions of the test specimens, the overlap length, the peeling angle, and also the test conditions are laid down in test standards and other guidelines. The test standards [DIN, EN, ASTM, ISO, BS, PSTC (Pressure Sensitive Tape Council)] are designed to give comparable results. Shear strength and tensile strength are expressed in N/mm^2 (strain/joint area), peel strength in N/mm (strain/specimen width). In general, adhesive joints are more resistant to shear and tensile forces than to peel and bending forces.

A distinction can be drawn between:

Static tests to failure under an increasing load
Static long-term strain test below the breaking strain (creep)
Dynamic tests with different loads and frequencies

The static test can be carried out with standard tensile testers that cover the appropriate force range, optionally with a data recorder to obtain a force plot. Dynamic tests require special vibrating devices with constant loads. After the destructive test further information can be gathered from the test specimen. The nature of the break is an important indication of the quality of a bond line. There are three types of failure:

Cohesive failure: break in the bond line
Adhesion failure: break between substrate surface and adhesive (poor adhesion)
Substrate failure, break in the substrate, the bond line is stronger than the substrate (structural bonding)

A combination of the above breakage patterns is possible. This is then indicated by a percentage figure (e.g., 60 % cohesive, 40 % adhesive failure). The above tests are also performed with exposure of the test specimens to extreme environments. Bonds are preferably tested for their resistance to:

Natural weathering
Climate variations (cycling)
Heat aging
Humidity aging
Corrosive atmospheres
Salt spray mist (automotive)
Underwater storage
Submersion in various chemicals such as petroleum, acids, and alkalis

The test conditions are generally much more severe than required for the actual final use of the bonded species. However these exaggerated test conditions deliver valuable information on the durability of the bonded structure in real life conditions. A good understanding has been developed for forecasting the bond line dependability on the basis of the results of aging tests.

The testing of specimens bonded under laboratory conditions is used to compare the performance of adhesives and substrates or the combination thereof, especially in quality-control laboratories. Under real-life conditions laboratory results may not be applicable. Surfaces of substrates, their geometry, curing temperatures, humidity, and many other factors may have an impact on the final bond quality. Therefore it is very important to perform a bond test in the final application even when the laboratory results were satisfactory. In many cases this is the only way to obtain information on the reliability of the bonded construction.

Testing of Anaerobic Adhesives. Testing standards and performance specifications for anaerobic adhesives and sealants have been established by government agencies and industrial organizations in several countries. In the United States there are military specifications for thread lockers, sealants, and retaining compounds. Many of these specifications are being superseded by commercial standards.

Mil-S-22473E, 12 April 1983 "Sealing, Locking and Retaining Compounds: (Single Component)" covers 15 of the earliest "Letter Grade" products. Specifications are set for color, viscosity, locking torque on 3/8-24 steel nuts and bolts and fluid tightness. The effects of immersion in a number of fluids, heat aging at 149 °C and hot strength at 149 °C (or 93 °C for some grades) are also measured. This specification calls for measurement of an "average locking torque" after 90, 180, 270 and 360° of turn.

Mil-S-46163A, 12 July 1983 "Sealing, Lubricating, and Wicking Compounds: Thread-Locking, Anaerobic, Single-Component" covers nine grades of product for sealing (Type I), lubricating (Type II), and wicking (Type III). Specifications are set for color, viscosity, locking torque (break and prevailing torque) on 3/8-16 steel, zinc- and cadmium-plated nuts and bolts, fluid tightness, lubricity, and "wicking" into preassembled fasteners. The immersion, heat aging, and hot strength tests are similar to those specified in Mil-S-22473E.

Mil-R-46082B, 10 June 1983 "Retaining Compounds Single Component, Anaerobic" (Amendment 6, 9 January 1990) covers three types of retaining compounds which are tested with a pin and collar compressive shear specimen. The three types vary primarily in viscosity although there are also some differences in heat resistance and strength. These products are subjected to immersion, heat aging and hot strength tests similar to those described above.

In Britain the Ministry of Defence specification DTD 5628-5633 covers test procedures and performance requirements for a range of products. Five strength bands and four viscosities from penetrating to thixotropic are defined. The torque strengths, including breakloose torque, are tested on M8 nuts and bolts and the shear strength in 12 mm pins and collars [201].

For an improved method of detecting the breakloose torque in a threaded component bonded with an anaerobic thread locker/sealer, see [202].

A British Standard BS 5292 has been prepared which relates to the use of anaerobic sealants on gas appliances.

In Germany standards have been published describing the "Compression Shear Test" (DIN 54452), "Dynamic Viscosity Determination of Anaerobic Adhesives by Rotational Viscometer" (DIN 54453), "Initial Breakaway Test at Bonded Threads" (DIN 54455) and "Torsion Shear Test" (DIN 54455).

In the United States the Industrial Fastener Institute has published standards for "Test Procedure for Locking Ability Performance of Non-metallic Locking Element Type Prevailing Torque Lock Screws" and "Test Procedure for the Locking Ability Performance of Chemical Coated Lock Screws." ASTM has published a "Standard Test Method for Shear Strength of Adhesives Using Pin-and-Collar Specimen" (ASTM D 4562-90, October 1990.)

ISO 10964 (August 15, 1993) "Adhesives – Anaerobic adhesives – Determination of torque strength of anaerobic adhesives on threaded fasteners" describes testing procedures for liquid and preapplied sealants.

9. Applications of Adhesives

It is possible here to select only typical examples for each subheading.

9.1. Bookbinding

Bookbinding with adhesives has played an important role since the beginning of the production of graphical products [185]. Originally, vegetable and animal raw materials were the main ingredients of adhesives, but a steady development of the adhesives took place to fulfill manufacturing requirements. Today, a range of adhesives, tailor-made for particular applications, is available. These applications include perfect binding, case making, casing in, back-lining and gluing-off of thread-stitched book blocks, as well as side-gluing and end-sheet tipping. The most important field is perfect binding.

Perfect Binding of Books. It is impossible to imagine the production of books, brochures and catalogues without perfect binding. New paper qualities such as high-weight coated (HWC) papers, lightweight coated (LWC) papers and recycling papers, high-quality papers such as matt-varnished papers and the increase of the production speed up to 300 books per minute require new bookbinding adhesives. Coated papers can have more than 50 % coat and therefore are difficult to bond. In general, the fiber structure of recycled papers is deteriorated by the recycling process, and these papers must be sized strongly, for instance, to withstand the pulling strain in offset printing, which causes a reduction of absorbency. Therefore, a longer setting time is needed for aqueous adhesives. Strong sizing can also lead to a change of the surface properties, which may cause adhesion problems. Occasional adhesion problems occur because of the often lavish designs of the graphic products.

Varnishing, laminating, embossing, and other refinements have the result that the adhesives can not reach the paper fibers, which are otherwise easy to glue.

Four adhesive types are used for perfect binding:

Glutin glues (animal glues)
Dispersion adhesives
Hot-melt adhesives
Reactive polyurethane hot-melt adhesives

Glutin adhesives are used in form of jellies which are processed at 50 – 70 °C. Due to a sol – gel transition, very fast setting is achieved and a high production speed is reached. However, the adhesion spectrum of glutin glues is normally not very wide.

In contrast, many synthetic polymers possess excellent adhesion characteristics. For example, poly(vinyl acetate) homopolymers combined with external plasticizers show high adhesion, sufficient cohesion, and are easy to use [186]. The improved productivity of the machines has led to the development of fast-drying systems (by high-frequency, IR heating, or gas dryers). The book block can be further processed after cooling for 4 – 5 min.

Hot-melt adhesives are especially useful when high production speeds are required. On rapid cooling, they set fast and achieve the necessary strength quickly. Hot-melt adhesives based on ethylene – vinyl acetate (EVA) copolymers are most commonly used in the graphical industry, although occasionally other thermoplastic polymers are used. Reactive polyurethane (PUR) hot-melt adhesives have proved to be especially useful for high-quality perfect bindings [187]. PUR hot-melt adhesives, which have a very good adhesion characteristics and excellent strength, are applied at 120 – 130 °C. After cooling (physical setting), they react with moisture (chemical setting) to give high-molecular compounds which are practically unmeltable. Besides good adhesion characteristics, they have high chemical resistance (e.g., to the oil of printing inks), high temperature resistance, and good aging resistance. PUR hot-melt adhesives require special premelters and application equipment because of their reactivity. The PUR adhesives combine the advantages of dispersions (e.g., good adhesion, high aging resistance) and of hot-melt adhesives (e.g. high production speeds) in a single system.

Another method of optimizing adhesion and cohesion is to use two different adhesives, one immediately after the other (two-shot application) [188]. The two adhesives can be of the same type (e.g., two dispersion or two hot-melt adhesives), or two different systems can be used (e.g., a dispersion primer followed by a hot-melt or PUR hot-melt adhesive).

Case Making. In case making, when the covering material consists of textiles, plastics film, or paper, as in the backlining of books, hot animal glues are used because they set rapidly by gelatinization and rapidly bond the narrow overlap of the coating material around the board, even under the brief contact pressure normally applied in the machine. In special cases, also emulsion-based adhesives are also used.

Casing In. Depending on the case material and the machine speed, normally emulsion adhesives [poly(vinyl acetate) or copolymer-based] with good flowing properties are used for casing in.

9.2. Adhesives for Packaging and Packaging Materials

Manufacture of Corrugated Board. For this purpose starch suspensions are used almost exclusively. Some of the starch is gelatinized under the heated corrugating rollers which form the corrugation, thus insuring high initial tack. The use of emulsion-based or hot-melt adhesives is confined to special cases. Hitherto, it has been discouraged by the relatively high price of these products, which only occasionally is compensated by other advantages.

Lamination of Paper and Board. Adhesives based on starch, dextrin, glutin and poly(vinyl alcohol), and also emulsion adhesives, mainly poly(vinyl acetate), are used for the lamination of paper and board. Only when high initial tack and a lay-flat effect are required are hot glues based on glutin still in use. Starch-based adhesives modified with silicate, casein-stabilized copolymer dispersions, and rubber latices are used in the lamination of paper to aluminum foils. Modified polyacrylate

solutions and reactive polyurethane adhesives are used mainly for paper-to-plastic lamination.

Adhesive Coating of Paper and Board. Pressure-sensitive coatings, for example, for self-adhesive labels and envelopes include natural rubber–resin combinations in solvents, polyacrylate emulsions, and hot-melt adhesives. Polyacrylate emulsions and hot-melt adhesives are becoming increasingly significant because they are solvent-free.

Heat-sealable coatings are applied from emulsions, solutions, or melts and are activated in different ways: heat-sealable coatings with delayed tack mainly by heat in the absence of heavy pressure, and typical heat-sealing coatings by pressure and heat applied to the bond area as contact or high-frequency heat.

Moisture-reactivated coatings are produced from dextrin glues, dextrin emulsions, mixed glues, and remoistenable hot-melt adhesives.

Bags, Sacks, Pouches, and Boxes. Starch-based adhesives and also emulsions of poly(vinyl acetate) homopolymers and copolymers or mixtures thereof are used in the manufacture of bags, pouches, and carrier bags, depending upon the type of materials (e.g., paper, plastic films, etc.), surface treatment, and the speed of the machine. Machine design factors necessitate the use of pastelike starch-based or emulsion-based adhesives for the bottom gluing of block-bottom or cross-bottom bags.

In making paper sacks, starch-based adhesives normally are used for the longitudinal seam and also for the bottom and bottom patching. For paper sacks with PE free film or inliner, emulsion-based synthetic resin adhesives are used. For the longitudinal seam of the inliner, hot-melt adhesives are used.

The manufacture of folding boxes has long been a domain for free-flowing, low- to medium-viscosity emulsion-based synthetic resin adhesives.

Envelopes. In general, the top-flap gumming of envelopes is made with modified conventional dextrin glues and dextrin–emulsion mixed glues, which dry more quickly and show better ability to stay flat for automatic enveloping. To an increasing extent, modified emulsions and remoistenable hot-melt adhesives are being used. Dextrin glues and synthetic resin emulsions normally are used for bottom-flap and window gluing. Gums for self-seal gumming are based on natural rubber. Self-adhesive top flaps are based on polyacrylate emulsions.

Adhesives for Automatic Packaging Machines. In automatic packaging, package production, filling, and closing are often carried out in a single machine. For this reason, very fast setting adhesives are used.

Considerable recovery forces occur in the closing of prefabricated boxes, particularly in seaming machines, so that hot-melt adhesives often have to be used in such cases. Emulsion-based adhesives are normally used for the dust-tight sealing of cases. Slide boxes, deep-freeze packs, etc., can be line- or spot-sealed with hot-melt adhesives.

Cartons are sealed with emulsion-based or hot-melt adhesives, depending on the length of the pressure belt and the quality of the cardboard. On modern, fast-running machines with up to 120 cases to be closed per minute, hot-melt adhesives are preferably used, due to their fast setting. An interesting combination is the simultaneous use of emulsion-based and hot-melt adhesives. In this case, a spot application of hot-melt adhesive performs the function of the pressure unit or compression section, whereas the actual bonding function is performed by emulsion-based adhesives, generally applied in line form.

Cigarette Manufacture. For gluing cigarette seams, depending on the application system, highly viscous or free-flowing starch glues or emulsion-based adhesives are used. Hot-melt and emulsion-based adhesives are used for cigarette-filter seams, since their viscosity, initial tack, and setting properties are compatible with the special conditions of this manufacturing step, both at low startup speeds and at maximum speeds of 600 m/min. Emulsion-based adhesives are used for bonding the filters to the cigarettes.

Adhesives for Laminated Films. Laminated films are produced by two techniques: lamination and extrusion. In lamination, the low-viscosity adhesive solution is applied by rolls to one of the films in a thickness of a few micrometers and dried. The two films are then combined in the laminator. The adhesives used

are either two-component or one-component, moisture-cross-linking polyurethane adhesives, depending on requirements (type of film, sterilization resistance, sealing seam strength, etc.). Besides the traditional solvent-based systems developments have been made in the direction of solvent-free systems (high-solids products) and of polyurethane emulsion-based systems.

In extrusion, a polymer melt is extruded onto a primary web. An improvement in adhesion or reduction in the extrusion temperature is obtained partly by applying an adhesive as primer to the primary web. Adhesives suitable for this purpose are similar to those used in a lamination. In coextrusion, two polymer melts are combined with one another. If required, a polymer primer is extruded between the two melts.

Bonding of Cellophane. Cellulose hydrate film is used for bag manufacturing or for wrapping operations. Because it readily takes up moisture in its unlacquered state, aqueous emulsion-based adhesives are used primarily for bonding. The addition of glycerol ensures they release their water only slowly so that the film stays flat. Lacquered cellophane is either bonded or sealed. The adhesives do not require any additives to keep the film flat because the film is protected by the lacquer. The adhesives are normally based on poly(vinyl acetate) copolymers or other flexible polymers. Where solvent-based or hot-melt adhesives are used, both types of film may be bonded with the same adhesive, because the absence of water eliminates the problem of keeping the film flat.

Manufacture of Polyethylene Sacks. The one-component and two-component polyurethane adhesives used for the production of laminated films (see above) are used for this purpose, depending on the type of machine.

Labeling of Glass. For labeling glass, dextrin, starch, and casein glues are used. With many machines, the adhesive used is required to show pickup ability, that is, the adhesive applied, for example, to a pallet must be tacky enough that it can pick up a label from the label magazine. Furthermore, the label must not slip after application, and any tendency to curl as a result of moistening must be counteracted. Dextrin glues are well endowed with these properties. In addition, by virtue of their high solubility in water, any glue that remains on the machine is easy to clean off. However, dextrin glues cannot be used where resistance to condensation, water, or ice is required (e.g., in breweries). Therefore, casein glues are mainly used in breweries. Although they are not as concentrated as dextrin glues (ca. 60 %), they develop a high initial tack, even on wet bottles, because they undergo a marked increase in viscosity on contact with the cold bottle. An additional reason for the use of casein adhesives is their wider adhesion range compared to dextrin adhesives. The latter adhere reliably to normal glass bottles, but their adhesion to coated or surface-treated glass bottles is not sufficient, so that casein adhesives have to be used.

Modern automatic high-performance labeling machines are capable of labeling between 500 and 1300 bottles per minute. At lower speeds, starch glues, which do not show such pronounced pick-up properties, are still used because of their lower cost. However, their higher water resistance can cause problems in bottle-washing machines for returnable bottles.

Labeling of Plastic Containers. The glues normally used for glass bottles cannot be used for plastic containers because they do not adhere sufficiently to plastic. Plastic bottles normally consist of polyethylene, polypropylene, poly(ethylene terephthalate), polycarbonate, poly(vinyl chloride), or polystyrene. Can-like containers and tablet tubes are made of polystyrene or polypropylene. Modified copolymer emulsion-based and hot-melt adhesives are used for labeling.

Although there are no major adhesion problems with PVC, PET, and PS, adhesives with stronger adhesive properties must be used for polyethylene and especially polypropylene. However, if the polyethylene surface is treated (e.g., exposed briefly to a gas flame) before labeling, it is possible to use the same adhesives as for PET or PVC.

9.3. Nonwovens Hygiene Industry

In general two types of adhesives are used for the manufacture of baby diapers, feminine-hygiene, and incontinence products. For simple construction purposes, hot-melt adhe-

sives based on amorphous poly(alpha-olefins) (APAOs) are used. High-quality constructions are produced with adhesives based on styrenic block copolymers. For bonding of elastic materials such as polyurethane foam, lycra and natural rubber strands, and hydrophilic and hydrophobic of nonwovens, pressure-sensitive adhesives (PSAs) based on styrenic block copolymers are used. Hot-melt adhesives are the most common types of adhesive. The most widely used synthetic block copolymers are styrene – butadiene – styrene (SBS), styrene – isoprene – styrene (SIS), and styrene – ethylene – butadiene – styrene (SEBS) with different styrene contents.

The adhesives are mainly applied intermittently (up to 650 pieces per minute for baby diapers and up to 1000 pieces per minute for feminine-hygiene products) at line speeds of up to 400 m/min. These requirements place high demands on the performance properties of the adhesives.

Construction Adhesives. APAO-based adhesives are mainly applied by slot nozzles on both the polyethylene backsheet and the nonwovens top sheet. Usual application temperatures are 125 – 140 °C.

The thermoplastic rubber-based adhesives are applied by application methods such as spiral spraying, fiberization, and melt blowing. Application temperatures are usually in the range of 140 – 165 °C.

Elastic Attachment Adhesives. These thermoplastic rubber-based adhesives are usually applied by spraying at 140 – 165 °C. As different elastic materials are used, different adhesives need to be formulated to give the right adhesion performance for each substrate.

Positioning adhesives for feminine-hygiene products are usually thermoplastic rubber-based, pressure-sensitive, and have low viscosities. The tack level can vary from very low to very high depending on the type of product and customer requirements. The positioning adhesive can be applied by both slot and fiberization applicators. The application temperatures depend on the type of substrate and vary from 120 to 170 °C.

9.4. Hygienic Papers

Four processing steps for the production of hygienic papers, (e.g. toilet paper, kitchen rolls) involve the use of adhesives:

Tube Winding. Mainly dextrin adhesives are used and/or plasticized homopolymeric poly(vinyl acetate) emulsions, but glutin glues are also used in special cases.

Pick-up adhesives bond the tissue to the Kraft paper tube. Depending on the machine systems the following adhesives are used: If the adhesive is applied directly to the tube by a slice (machine speed up to 400 m/min), aqueous colloidal solution systems at room temperature are normally used. If the adhesive is applied directly to the tube by a nozzle (machine speed up to 450 m/min), aqueous polyol-based adhesives are often used at room temperature.

When the adhesive is applied by a slice to the application roller, which transfers the glue to the tube (machine speed up to 650 m/min), hot-melt adhesives are used at 60 – 80 °C.

For high speed machines (up to 850 m/min), in which the adhesive is applied directly as a strip by means of a nozzle (temperature of the nozzle 80 °C), aqueous colloidal solution systems are used.

Laminating Adhesives. Aqueous adhesives based on cellulose or poly(vinyl alcohol) for the ply lamination of tissue papers must give clean machinability, good initial tack, and reliable bonding strength of the tissue laminates.

Tail Tie. For this application aqueous adhesives based on cellulose or poly(vinyl alcohol) are used. For the tail tie of tissue paper rolls, products with high wet tack, transparent film, and a low final bond strength are necessary.

9.5. Gluing of Wood and Wooden Materials

Today for the assembly gluing of wood, for gluing veneers, plastic sheets, and films, and for the manufacture of wood-based materials (chipboard, plywood, hardboard, profiles), synthetic

adhesives are used almost exclusively. The traditional use of adhesives based on natural products (glutin and casein glues) is confined to a few special cases only (for example, violin making).

Poly(vinyl acetate) emulsion "white glues" are used widely for the gluing of wood and wood-based materials. They generally contain small quantities of solvents and/or plasticizers to adjust the film-forming temperature and chalk as a pH buffer and filler. They have a solids content of approximately 50 – 65 % and a film-forming temperature of 0 to 15 °C. Special components may be added to increase the setting rate or to prolong the open time. The application weight is 100 – 200 g/m^2, the open time 5 – 25 min, and the clamping time 5 – 45 min for a compressive force of 5 – 20 N/cm^2. The exact figures strongly depend on the glue coating weight and the type of substrate.

Bonds with higher water resistance can be achieved by using special blends or two-component emulsion glues. The second component may be a diisocyanate or particularly an inorganic salt (usually, aluminum nitrate). These hardeners, added in a quantity of at least 5 %, improve the moisture resistance of the joint. However, their addition limits the pot life.

Normal glues develop EN 204/205 Class D2 strengths which are adequate for all indoor applications, for example, for the assembly gluing of furniture and for laminating plastic sheets. Self-cross-linking one- or two-component poly(vinyl acetate) glues, which develop Class D3 and D4 strengths according to the same European standard, may be used for gluing in moist atmospheres (bathrooms) and for exterior assembly gluing (windows, doors).

Furniture Foil Adhesives. These adhesives consist primarily of vinyl acetate – ethylene copolymer emulsions. Rigid PVC and melamine – paper foils, generally 0.2 – 0.4 mm thick, are applied to wood-based materials for decorative purposes. The adhesives must exhibit high tack and high resistance to heat and cold and must counteract the shrinkage of the film (application weight 60 – 100 g/m^2).

Hot-melt adhesives are mainly used for automatic edge-banding applications to bond edge materials to particle board, as well as for profile wrapping with foils, paper, and veneer.

Increasingly, hot-melt adhesives also are being used for the postforming process. Immediately after surface lamination, the overhanging laminate is bonded to the contoured panel edge without an additional adhesive joint.

Hot-melt adhesives are applied on edge-banding machines, profile-wrapping machines, and postforming machines. The adhesive is applied to the substrates with special rollers or slot nozzles. The joint between the cover and the core material is achieved by applying pressure with a roller system while the adhesive sets.

In assembly processes, such as furniture or door manufacture, the hot-melt adhesive is applied in spots or lines by hand or with automatic guns. Often the hot-melt adhesive is exclusively used as an additional assembly support due to its high initial strength, while poly(vinyl acetate) glue is used for achieving the final strength (two-shot process). Hot-melt adhesives for the edge-banding and postforming process are highly viscous products, often filler-free or with a filler content of up to 50 %. For profile wrapping, low-viscosity hot-melt adhesives are used, sometimes with fillers. For assembly bonding, a wide range of assembly hot-melt adhesives varying in viscosity, setting time, and open time is available for different equipment and uses.

As adhesives based on ethylene – vinyl acetate copolymers cover a very wide range of applications, they are used in large quantities. In the case of higher demands on the bond, polyamide- or polyolefin-based hot-melt adhesives are recommended. Highest bonding quality regarding heat and cold resistance, bonding strength, and waterproofness are achieved by using polyurethane-based, moisture-reactive hot-melt adhesives.

EVA hot-melt adhesives have heat resistance up to 85 °C, polyolefin and polyamide hot-melt adhesives up to 130 °C, and reactive polyurethane hot-melt adhesives up to 150 °C. The cold resistance lies between − 20 and − 30 °C; in the case of polyurethane-based hot-melt adhesives, it is even lower than − 30 °C.

Urea formaldehyde (UF) resin glues are the most widely used adhesives in woodworking and are preferably applied by the hot-glue technique. They are marketed as preconden-

sates in the form of 50 – 66 % solutions or as dry powders that must be dissolved in water. Curing aids can be added. In veneering, contact times as short as 30 s are possible for press temperatures of 100 – 120 °C. The most common additive is ammonium chloride. The amount of hardener governs both setting time and pot life. Glue joints in thick boards can be set by high-frequency heating.

For gluing plywood, the UF resins are generally mixed with extenders such as rye flour, followed by the addition of curing aids, the type and amount of which governs the setting characteristics at the processing temperature and pressure. The glues thus prepared are applied to the dry veneers (moisture content 6 – 12 %) by a glue spreader (application weight 120 – 200 g/m^2), and the glue-coated veneers are assembled and then glued in multilayer hot presses or high-speed single-layer presses at 100 – 160 °C and 60 – 200 N/cm^2, depending on the type of wood. For particle board production, unextended UF resins are used preferably. The particles are coated with glue by spraying, the particles of the center layer being coated with less resin than the particles of the two surface layers. Average glue resin content is ca. 10 % (i.e., 6 – 8 % for the center layer and 8 – 12 % for the surface layers). The glue-coated particles are first spread to form a three-layer cake, precompressed, and then compressed in hot presses to form particle board.

UF glues ideally satisfy the requirements for interior use but are unsuitable for exterior application. The requirement for low formaldehyde content must be considered by all producers of particle board. As plywood and veneer glues, with regard to water resistance, UF resins satisfy the requirements of DIN 68705 and EN 314, category IF, and as particle-board binders they meet the requirements of DIN 68763, category V 20.

The glues are cheap, easy to apply, and therefore suitable for the mass production of wood-based materials.

Melamine resin glues are important in the woodworking field when weatherproof glue joints according to DIN 68705, category AW at relatively low press temperatures (under 100 °C) are required. With added extenders moisture-proof glue joints can be obtained that meet the requirements of the same DIN category IF, at press temperatures above 75 °C.

Melamine – Formaldehyde (MF) Resins. The largest field of application for melamine formaldehyde (MF) resins is the manufacture of decorative laminates and the surface finishing of chipboard, hardboard, and profiles. Special papers with weights of 18 – 150 g/m^2 are impregnated with MF resins, dried, and then pressed onto the substrates at 130 – 180 °C. Their colorless transparency, hardness, chemical resistance, and absence of yellowing have made these resins particularly suitable for surface finishing. For technical applications including, e.g., concrete form-work boards, they are also applied by the wet-resin process, in which the resin solution is applied to the surface and cured under heat and pressure.

Phenolic resin glues, for cost reasons generally derived from phenol cresol mixtures, are used for the hot gluing of plywood, the manufacture of chipboard, and as binders for fiberboard. They are marketed in liquid form. Their shelf life is limited to about six months. They set at 130 – 180 °C, generally with addition of hardeners. For setting at room temperature, the addition of a special hardener (usually *p*-toluenesulfonic acid) is essential. The use of phenolic resins requires a relatively low moisture content of the wood (6 – 10 %).

Joints based on phenolic resin glues are of high quality and weatherproof. They are recommended for gluing wood to metal (metal-clad wood).

Resorcinol resin glues set without the assistance of heat under mildly alkaline conditions. Therefore, no damage is caused to the wood by acid hardeners, and there are no restrictions on the moisture content of the wood up to 18 %. The resins can be cured with paraformaldehyde. Wood-to-wood glue joints with resorcinol resins are among the strongest and are weatherproof and resistant to solvents, oils, and fats. For reasons of economy, mixed condensates of resorcinol and phenol are used instead of pure resorcinol.

Contact Adhesives. In countries with a high standard of mechanization, contact adhesives

based on chlorinated rubber for woodwork are used only for on-site repairs and for special purposes, e.g., for gluing plastic sheets or veneers onto rounded substrates. Here, contact adhesives are widely replaced by poly(vinyl acetate)-based wood glues. However, in less developed countries, contact adhesives are still widely used for veneering and laminating plastic sheets to wooden substrates. Their advantage over all other wood glues is the high bonding strength achieved virtually immediately after joining under short-term pressure (several seconds) without the need for sophisticated equipment.

Polyurethane Glues. The search for formaldehyde-free binders resulted in a new generation of polyurethane-based glues for chipboard production. The usage of polyurethane based adhesives for assembly of wooden materials has also increased. These liquid polyurethane adhesives are single-component adhesives that harden by a chemical cross-linking reaction which is initiated by moisture in the material. The water resistance of wooden joint fulfills the requirements of EN 204, D4. Furthermore, the adhesive joint shows high resistance to a variety of organic solvents, weak acids, and alkalis.

Over-all Quality Standards for Wood Glues. There are several national and European standards for the adhesives used in woodworking, of which the following are the most important: EN 204, EN 205, DIN 53255, DIN 68705, and DIN 68761 – 765.

9.6. Footwear Adhesives

One of the most important methods of assembling shoe components is adhesive bonding. In 1949 polychloroprene adhesives replaced the nitrocellulose solutions that had been introduced in 1906. The almost complete versatility of the polychloroprenes allowed leather, textiles, and other natural substances (until then the only shoe materials) to be supplemented by other materials, such as various rubbers and synthetics, or to be replaced altogether, as in the case of toe puffs, counter stiffeners, or heels. The way was thus opened for an astounding development in fashion and shoemaking techniques. Adhesive-based processes, supported by new machines and equipment, led to new bottom-attachment systems, simplified the production of footwear, and drastically reduced the number of production operations. Since 1970 a position of comparable importance has been reached by polyurethane adhesives.

Other adhesives for shoe manufacturing are solvent adhesives based on natural rubber or SBS or SIS block copolymers, dispersions of polyacrylates and poly(vinyl acetate), and a range of latex and hot-melt adhesives.

Closing Room Adhesives. These adhesives are light-colored and nonstaining solutions (or latices) of natural or synthetic rubber; other polymer dispersions are also possible. Wet-stick and pressure-sensitive bondings predominate. Also PSA hot-melt adhesives are of increasing importance for these applications. If higher strengths are demanded of the bonds, for instance, for replacing stitched structural seams, the requirements are met by two-way contact adhesives or by adhesives weldable in the high-frequency process. Ethylene – vinyl acetate hot-melt adhesives are used for applying backings and for sticking-in toe puffs and counter stiffeners, whereas polyamide hot-melt adhesives are used for folding, edge binding, including french binding, etc.

The components to be bonded (linings, interlinings and other reinforcements, and also toe puffs and counter stiffeners) can be precoated with adhesive and then ironed in.

The Lasting Operation. Apart from the bottom attachment, the lasting operation produces the most vital structural bond in the shoe. It involves the fastening of the upper material over the margin of the insole and is subjected to considerable stress; there is normally no supplementary stitching, tack-driving or stapling. A common lasting system is combined pulling-over and cement-lasting with automatic injection of hot-melt adhesive; this is mainly a rapid-setting crystalline polyester or the more flexible polyamide, both supplied in rod or granule form. Lasting by contact bonding with polychloroprene adhesives (or in light shoes also with natural rubber solutions and latices) is limited to particular constructions.

Bonding Soles to the Lasted Uppers. Polychloroprene and polyurethane solvent adhesives, occasionally also dispersions of the same polymers, are used for this purpose. Various pretreatments are used to improve the bond: application of a thin first coat of adhesive, especially for absorbent surfaces; priming, in particular the halogenation of vulcanized rubber and thermoplastic rubber soling; the use of base-coat primers for nylon and other synthetics, as well as UV-curing primers for EVA and other substrates in athletic footwear.

Depending on the required productivity, quality, and performance a wide variety of processes are used in sole bonding. As an example for a contact bond, the single-component adhesive is applied to the sole, usually in advance. The soles can be stored (dust-free) until required in the production process. On the lasted margin of the shoe upper, the adhesive is usually a two-component mix containing isocyanate hardener; bonding must be carried out within the specified open-assembly time.

For bonding with heat activation, the sole is activated by IR irradiation or rapid flash activation: the activation time may be 2 – 6 s, and a surface temperature 55 – 80 °C can be reached. During the process it is the adhesive film that is heated, rather than the sole, which remains cooler. This ensures a more rapid development of bond strength. Soft soles that tend to deform when hot can be bonded at room temperature or with adhesives that have a low activation temperature.

For the various molding-on processes, such as the direct injection molding of thermoplastic rubber or PVC, the vulcanizing-on of rubber, and the low-pressure reaction molding of integral-skin cellular polyurethane, adhesives can seldom be dispensed with: the lasted margin of the upper is coated with a polyurethane adhesive, often containing a pre-mixed latent hardener, or with a self-vulcanizing synthetic rubber solution compounded to match the vulcanization system of the soling compound.

With moisture curing polyurethane hot-melt adhesives a new innovative technology has been introduced in the sole-bonding process. It can be used as a one-way bonding system or as a two-way contact adhesive, applied either to the sole or to the upper. In this process, an adhesive coat must be applied on the other substrate.

Adhesives for Shoe Repairs. These adhesives must be almost universally applicable, because widely differing shoe types and material combinations must be repaired. For this reason, one-component polychloroprene-based adhesives are used almost exclusively, though for PVC and some other plastics materials polyurethane adhesives are quite common.

Testing. In Europe adhesive properties are tested according to European standards (CEN) EN 522, EN 1391, and EN 1392. Specified standard test materials can be obtained from the various research institutes of the European shoe industry.

9.7. Bonding of Plastics

Plastics are bonded to one another or to other materials. They differ widely in their affinity for bonding. Some plastics are easy to bond (e.g., PVC-U, ABS, PS), whereas others can be bonded only after special preparation (e.g., PTFE). On account of the low polarity and surface tension of certain plastics (e.g., polyolefins) there are still no adhesives for pipe joints which are durably resistant to shear strain and pressure. The choice of adhesive is determined by the substrate and the mechanical, thermal, and chemical requirements [69–75].

Poly(Vinyl Chloride). Rigid PVC (PVC-U) and chlorinated PVC (PVC-C) pipes, sheets, and films are used worldwide in the construction industry. They are joined by adhesives consisting of PVC solutions in a mixture of solvents, which operate by the principle of diffusion bonding. The bond is established by diffusion of the adhesive into the surfaces and the temporary dissolution of the PVC (cold swell welding).

For the bonding of uncalibrated pipe joints, adhesives with gap-filling properties are used, in which PVC of a certain molecular mass is dissolved in a solvent consisting predominantly of THF, cyclohexanone, or *N*-methylpyrrolidone. The viscosity range is 2000 – 3500 mPa s. The application time of the adhesive ranges from 1 to 5 min. The adhesives are preferably made thixotropic so that they do not run off the surfaces to be joined after application and to avoid

the damage to the plastic material because of accumulation of adhesive (the excess solvent can cause tensile corrosion). After preliminary cleaning of pipe and fitting with solvent (cleaning and dissolution) and application of the adhesive to both sides, the pipe and the fitting immediately are fitted together without turning. The bond is established by diffusion of the adhesive into the surfaces and temporary dissolution of the PVC (diffusion bonding).

PVC adhesives, usually consisting of solutions of post-chlorinated PVC in methylene chloride, are used in the case of inorganic acids as flow-through media in PVC pipe because of their better chemical resistance. Since PVC adhesives have no gap-filling properties a special application technique is required. This priming method is little used today.

Contact adhesives based on polychlorobutadiene or polyurethane are used for large-area bonds between PVC-U and PVC-C sheets and wood or metal.

Vessels are often lined with thin PVC-U and PVC-C films (1 – 2 mm thick). Contact adhesives are used with usual application techniques. For bonding cooling tower films, special adhesive solutions, which are harmonized in viscosity and thixotropy with the processing techniques (roll or pot application), analogous to PVC pipe adhesives, are used.

Adhesives for bonding plasticized (flexible) PVC (PVC-P) films are adhesive solutions based on THF (80 – 90 %) and PVC-P (10 – 20 %). Adhesives based on nitrile rubber or polyurethane in a plasticizer-resistant formulation for the bonding of PVC-P films made from differently formulated compounds are also suitable.

Adhesives based on polymethacrylates and vinyl copolymers are used for the continuous bonding of PVC-P films to metal sheets (coil coating). In this process, the adhesive is applied by machine to the cleaned sheets, the solvent is removed, and the film subsequently is rolled into the bed of adhesive heated to 140 – 180 °C.

Polystyrene, Styrene – Acrylonitrile Copolymers, and Styrene – Butadiene Copolymers. These plastics may be bonded to themselves or to one another simply by treating the surfaces to be joined with pure solvents, such as dichloromethane, ethyl acetate, or 2-butanone. However, this method of bonding, which also is known as solvent welding, does involve the risk of material corrosion. Therefore, it is advisable to use solutions of polymer raw materials in mixtures of organic solvents with a low risk of material corrosion. Depending on the field of application, especially in combining different materials, contact and nitrile-rubber adhesives containing aliphatic hydrocarbons as solvents also may be used. Pipes of ABS/ASA (ASA: acrylonitrile – styrene – acrylic ester polymer) for high-temperature wastewater run-off systems (max. 90 °C) preferably are joined with solutions of ABS/ASA in acetone or 2-butanone, although they also may be bonded with THF – PVC systems. The solutions are of medium viscosity (max. 2000 mPa s) and have a predominantly thixotropic rheology.

Solutions of ABS in 2-butanone are preferred for use in pressure applications, such as compressed-air conveying systems. As with PVC, the bond is established by diffusion.

Rigid polystyrene foam is used for the manufacture of composite sheets, for example, for containers and prefabricated building boards. The rigid foam is combined with metals, wood-based materials, asbestos, cement, and plastic sheets. Polyurethane adhesives are particularly effective in this field.

Polyolefins. Polyethylene, polypropylene, and polybutene can be bonded only after treatment to increase the surface energy, generally by oxidation, and make the surfaces receptive to bonding. Pretreatment can be carried out with an oxidizing flame, with oxidizing chemicals, or by electrical discharge.

Nowadays, the flaming process is rarely used: in the lining of containers with polyethylene and in the printing of bottles (Kreidel process). Among the chemical pretreatments, immersion in chromosulfuric acid (for a few seconds to a few minutes), followed by careful rinsing with water has proved successful. Thin plastic layers for the production of laminated films for use as packaging materials are best pretreated by corona discharge.

The pretreated polyolefins can be bonded with contact adhesives, epoxy resin adhesives, one- and two-component polyurethane adhesives, and hot-melt adhesives.

Polyamides are bonded with concentrated (ca. 85 %) formic acid. Two-component polyurethane or epoxy resin adhesives are suitable for bonding to metals, for example, for holding bearing bushings in place.

Polymethacrylates can be bonded by treating the surfaces to be joined with a mixture of dichloromethane and dichloroethylene. However, this does involve the risk of material corrosion. In such cases, polymerization adhesives cured by light can be used. Polyurethane, epoxy, and contact adhesives are also suitable.

Fiberglass-Reinforced Plastics. To obtain high-quality pipe connections, the surfaces to be joined must be roughened and the pipes carefully tapered. Polyester adhesives or thermosetting epoxy resin adhesives are best suited for bonding. A pressure of 50 – 100 N/cm^2 is applied to the joined surfaces.

Fluoropolymers. There are no known adhesives for fluoropolymers that give bonds of adequate strength without pretreatment. Simple, low-quality bonds can be obtained with contact adhesives. After chemical pretreatment, for example, with a solution of an alkali metal naphthalenide in THF, polyfluorocarbons can be bonded with high strength by using epoxy and polyurethane adhesives.

Curable Molding Compounds. High-strength bonds involving these plastics are obtained with epoxy resin adhesives. The adherents must be roughened lightly and thoroughly cleaned beforehand. Laminates, including decorative laminates, of phenolic resin- or melamine resin-impregnated papers or fabrics can be bonded with contact adhesives.

9.8. Bonding of Elastomers

In the rubber industry, a fundamental distinction is drawn between "bonding" and "adhesion". Whereas the adhesion of generally vulcanized rubber articles to one another or to metals or plastics is solely a function of the adhesive used, bonding is a process in which vulcanization of the rubber and, at the same time, adhesion between rubber and substrate are obtained by the action of heat and pressure (→ Tires).

9.8.1. Adhesion of Rubber

Contact Adhesives. Nowadays, rubber solutions based on natural rubber or styrene – butadiene rubber, optionally in conjunction with regenerate and depolymerized rubber, are used for large-area bonding where adhesion does not have to meet stringent requirements, as is the case, for example, with the lining of vessels, containers, etc. with rubber.

Today, multipurpose adhesives based on polychloroprene rubber generally are used as adhesives for rubber articles.

Reactive Adhesives. Epoxy and polyurethane adhesives are suitable for bonding polar elastomers, such as nitrile rubber and chloroprene rubber. However, epoxy adhesives form a relatively rigid bond so that they are suitable only for bonding to rigid substrates. In contrast, polyurethane adhesives form elastic bonds and therefore are used for rubber-to-rubber and rubber-to-leather bonding, for example, in the manufacture of profiles and in the shoe industry.

Polyurethane adhesives also are suitable for bonding nonpolar elastomers, for example, natural rubber, styrene – butadiene rubber, or ethylene – propylene terpolymers, after chemical pretreatment of the surface.

Polymerization adhesives based on α-cyanoacrylates (see page 22) are suitable for special bonds involving rubber, because they enable bonds of high strength to be obtained quickly and easily. Medium-viscosity types are preferred for rubber-to-rubber bonds by virtue of the minimal hardening of the joint. In the rubber industry, for example, the adhesives are used for bonding profiles to one another and also for repair work.

Because of the increasingly stringent requirements that rubber articles have had to satisfy over the past 20 years, the bonding process is preferred in the manufacture of rubber – metal composites.

9.8.2. Bonding of Rubber

Rubber-to-Rubber Bonding. In the bonding of unvulcanized rubber mixtures to one another, there is generally no need to use adhesives when the mixtures to be combined with

one another are identical or similar in composition. However, adhesives have to be used for combining different types with one another. Various bonding agents based on halogenated polymers are available commercially for this purpose and also may be used for bonding vulcanized to unvulcanized articles.

Rubber-to-Fabric Bonding. Rubber-to-fabric bonding is of considerable commercial significance in the tire industry and industrial rubber goods such as conveyor belts and rubberized fabrics. In the tire industry, the so-called resorcinol – formaldehyde (RF) latices are still used predominantly for bonding rayon, whereas mainly resorcinol – formaldehyde – vinylpyridine latices are used for bonding nylon and adhesively finished polyester yarns, which, unless specially pretreated, adhere very poorly to rubber.

In industrial rubber goods, which exhibit considerably greater variations in rubber composition, solutions of unvulcanized rubber mixtures are used. They are applied to the fabric as a first coat with the addition of polyisocyanates to improve adhesion. Directly adhering rubber mixtures containing resorcinol – formaldehyde donors and an acidic silica filler are also used for the production of fabric-reinforced rubber materials.

Rubber-to-Metal Bonding. In the Ebonit or hard rubber process [76], the bonding agent is a reaction product of natural or synthetic rubber with 30 – 40 % sulfur, which is thermoplastic in character, adheres firmly to metal, and provides for good adhesion to soft rubber. This process is still in use today in the lining of vessels and, to a certain extent, in the manufacture of large-diameter rolls.

The brass process makes use of the fact that electrodeposited brass of certain composition and crystal structure is capable of directly bonding rubber mixtures, providing their composition is compatible with the adhesion process [77]. Whereas today the brass process is of only minor significance for the production of rubber – metal composites, it is widely used in tire manufacture for bonding the bead wires and for bonding the carcass mixture of steel cord.

Certain polyisocyanate adhesives allow bonding of rubber to metal with far less technical effort than by the brass process. However, polyisocyanates are extremely sensitive to atmospheric moisture and react with compounds containing OH and NH_2 groups, such as antiagers. This reaction leads to a weakening of adhesion.

Nowadays, rubber – metal composites are produced with bonding agents in which the polymer base is usually a halogenated polymer, for example, a mixture of chlorinated and brominated polybutadiene. After the film of bonding agents applied to the metal component has dried, the metal component is bonded to the rubber mixture during the vulcanization process.

Mechanical and/or chemical pretreatment of the metal is essential for corrosion-resistant bonding (for the effect on bonding of the blasting medium used for blasting, see [78]).

The fillers in the rubber have no significant effect on bonding. However, soft rubber mixtures (30 – 40 Shore A) are more difficult to bond than hard rubber mixtures because of their high plasticizer content. The degree of vulcanization is another determining factor as far as the quality of bonding is concerned [79]. Bonding errors generally occur if the mixture is scorched before it comes into contact with the bonding agent surface or if the mixture is undervulcanized or severely overheated [80].

9.9. Bonding of Metals

The adhesives used for bonding metals are preferably reactive adhesives, predominantly epoxies, phenolics, acrylates, polyurethanes, although poly(vinyl chloride) plastisols, MS polymers, and rubber adhesives also are used for elastic bonds [81–85]. The range of bond strengths obtainable extends from high-strength, structural bonds (tensile shear strength ca. 40 N/mm^2) to highly elastic adhesive sealing compounds (tensile shear strength ca. 1 N/mm^2). However, the strength of a bond depends to a large extent upon the nature and direction of the forces acting upon it and on the temperature. Because the intrinsic strength of the cured adhesive resins is not comparable with that of metals, provision must be made for sufficiently large joint areas. Accordingly, the design of adhesive joints in metals must be appropriate for bonding. Resistance to aging and corrosion

depends on the nature of the surface pretreatment and on the type of adhesive used.

Epoxies, polyurethanes, and acrylates represent the principal types of adhesive for structural bonding of plastics and metals. These technologies compete for various applications in the transportation and marine industries because of their strength, good environmental durability and cost effectiveness. Historically, urethanes were chosen for low-temperature applications because their hard segment/soft segment structure typically allows them to retain flexibility in cold environments. Conversely, epoxies were preferred for high-temperature environments because of their strength and high cross-link density. Methacrylates fill the gap between these two technologies. They offer good resistance to high and low temperatures, and they provide the distinct advantages of rapid curing at room temperature, less sensitivity to mixing ratio and higher tolerance of surface contamination. They are proven performers in the transportation and marine industries. Typical applications include bonding fiber-reinforced plastics to metal.

The aeroplane industry was the first to incorporate metal bonding in assembly procedures on a significant scale. The increasing use of high-strength lightweight metals which cannot be satisfactorily welded and the reduction in overall weight through the introduction of light-gauge constructions were other important influencing factors. Light-gauge sheets (skins for fuselage and wings, control surfaces, etc.) could be stiffened more effectively by cementing onto corresponding profiles than by riveting. The problem of reinforced openings (windows, door frames) and of distributing stresses over large cross-sectional areas (rotor blades) was satisfactorily solved by multilayer construction, especially supporting-core and sandwich constructions, the widespread application of which actually was made possible by bonding. In this method, high-shear cores of various structures (e.g., honeycomb), are bonded to thin cover layers or skins of aluminum and other materials. This gives a lightweight, nondenting, torsion-resistant construction suitable for aircraft floors and wings. Suitable adhesives are phenolic – poly(vinyl formal) and epoxy adhesives and also epoxy – nylon adhesive films.

Vehicle manufacture (automobiles, railroad vehicles) is another significant application for metal-to-metal bonding.

In *lightweight metal constructions,* tubes and hollow profiles of any cross section can be designed and bonded as socket joints. Door and window frames are made from steel and aluminum profiles with angles bonded in place (epoxy adhesives), a heat-insulating intermediate layer being applied by bonding or made by casting with an adhesive (polyurethane, epoxy adhesives).

In *bridge building,* adhesive joints (epoxies, polyesters) are used in combination with high-strength, on-torque threaded fasteners (to absorb peel forces) for load-bearing steel constructions.

In the *electrical industry,* it is above all the bonding of sheet packs (dynamo sheets, transformers, motors) and the fixing of small parts (ferrite cores) that are increasing in significance (epoxy resins, cyanoacrylates). Adhesives (epoxy resins) containing conductive additives also are used, for example, for printed circuits.

In *machine construction* and *instrument* and *tool manufacture,* plain bearings, axle bearing guides, bushings, etc., are made by bonding, and punches are cemented into stamping tools with epoxy resins, cyanoacrylates, and acrylate adhesives. Screws, gear wheels, shafts, etc., are secured with anaerobic adhesives.

Adhesive pastes are used as *repair kits,* often in combination with woven glass-filament cloth for reinforcement. In this way, bodywork is repaired, worn surfaces are renewed, and pipes are sealed (epoxies, unsaturated polyester resins).

The sandwich construction method mentioned above involves joining *metals to other materials* by bonding. Further examples include the bonding of brake linings (phenolic adhesives) and compound materials in ski manufacture, where aluminum is bonded to plastics, wood, etc. (phenolic and epoxy adhesives). Highly alloyed steels, beryllium and titanium alloys, and other special metals can be bonded with adhesives (e.g., polyimides, polybenzimidazoles) that have comparable high-temperature resistance.

9.10. Adhesives for Wallcoverings

Wallcoverings, classified by EN 233 – 235 [133], consist of a variety of materials: paper, textiles, glass, plastics (PVC, PE, PS, PU), ceramics, wood, cork, metals, leather. They are attached by hand in the form of sheets (wallpapers), tiles, or profiles to masonry, plaster, concrete, plasterboard and gypsum wallboard, wood, and metals.

For ease in do-it-yourself projects (adjustability, open time, easy application, etc.) and because most substrates to which the coverings are bonded are capable of absorbing moisture, it is preferable to use water-based adhesives in the form of solutions and emulsions. Solvent-containing adhesives are only used on nonporous substrates, for example, metals [86], [87].

The adhesives are based on methyl cellulose, starch ethers, carboxymethyl cellulose, pregelatinized starch, poly(vinyl acetate), polyacrylate, styrene – butadiene latices, polychlorobutadiene, and polyurethanes. The viscosity of the adhesives covers the range from fluid to pasty.

Wallpapers include those with a PVC or metal surface and rough-textured plain wallpapers. They are applied with pastes of pregelatinized starch, starch ethers, carboxymethyl or methyl cellulose in the form of 2 – 10 % solutions. For rough-textured plain wallpapers and heavy wallpapers, moisture resistance and tack are increased by utilizing poly(vinyl acetate) redispersion powders. High solid, emulsion-based adhesives, optionally in conjunction with resin-enhanced pastes (special purpose pastes), are used preferably for heavy vinyl- and metal-faced wallpapers.

Light *textile fabric wallcoverings* are hung with special fabric wallcovering adhesives. Special-purpose pastes containing 10 – 20 % of emulsion-based adhesives also are used.

Heavy wallcoverings of unbacked PVC (1000 g/m^2 or more) can be applied with adhesives based on acrylate or poly(vinyl acetate) copolymer emulsions. The same applies to *metal foils* that are applied underneath wallpaper as a vapor barrier.

Polystyrene and *polyurethane foam* and *mineral wool tiles* are applied to interior and exterior for decoration and insulation purposes (sound and heat). Solventless adhesives based on poly(vinyl acetate), polyacrylate, or styrene – butadiene copolymer emulsions are preferred for this purpose. The viscosity of the adhesives must be adjusted to give the required wet tack.

Ceramic wall tiles are applied either with cement mortar adhesives or with adhesives based on styrene – butadiene copolymer or polyacrylate emulsions. Tile adhesives must be pasty and thixotropic to prevent the tiles from slipping but allow positioning.

Wood panels, chipboard, and similar wooden materials can be fixed with aqueous adhesives based on poly(vinyl acetate) or polyacrylate emulsion. The adhesives must be pasty and have high initial strength. In some cases they are applied from cartridges. Also contact adhesives, special reactive systems (hybrid silicone), and hot-melt adhesives are utilized.

9.11. Floorcovering Adhesives

Flooring adhesives are used for attaching floor coverings to a variety of substrates. The adhesives must develop a strong and durable bond between the floor covering and the substrate. They should not adversely affect coverings, supports and substrates, and after application, should remain odorless and have low emissions. Usually flooring adhesives are applied to the substrate by hand with trowels or sometimes rollers.

Environmental and occupational-health legislation has resulted in a major shift from organic solutions to aqueous emulsions of polymeric compounds [88], and the use of waterborne adhesives is accepted as the state-of-the-art for most floor covering installations. Waterborne flooring adhesives are often based on acrylic copolymers, vinyl acetate – acrylics, vinyl acetate – ethylene – acrylics, or styrene – butadiene rubber latex. They commonly contain natural (e.g., colophony and colophony esters) or synthetic resins (e.g., hydrocarbon resins) and inorganic fillers. In recent years the content of solvent has been reduced to below 5 wt %. The use of high-boiling solvents (glycol ethers, liquid hydrocarbons) has been adopted to some extent for the formulation of solvent-free flooring adhesives [89]. There is now a move to eliminate high-boiling substances and even traces of volatile contaminants from the

adhesives [90]. Several European manufacturers have established a chamber test method to record VOC and to classify low-emission products for flooring [92], [91]. Today solvent-based products are only needed for special applications (e.g., water-sensitive substrates).

Linoleum Adhesives. Linoleum generally is laid with waterborne adhesives based on acrylic emulsions or SBR latex. They contain higher amounts of inert inorganic fillers, and natural and/or synthetic resin is used to accelerate initial tack. Linoleum adhesives have to set rapidly to avoid expansion or shrinkage of the covering. Two-component adhesives consisting of one polymer dispersion and a second cement preparation are available to adhere linoleum to nonabsorbent substrates.

Parquet adhesives can be cold- or hot-spread compositions. The former can be classified as waterborne, solvent-borne, or reactive. The first two types are commonly based on poly(vinyl acetate) emulsions in water or as solutions in organic solvents. Reactive systems are solvent-free two-pack polyurethane adhesives or epoxy resin adhesives. They are preferred for all parquet and wood types which are sensitive to water. All adhesives are required to show high cohesive strength but certain plasticity to absorb movements of the wood through shrinking and swelling in response to changes in atmospheric humidity without failure of the joint. Hot-spread adhesives, which are bituminous or tar-based, are increasingly being replaced by the cold-spread types.

Adhesives for Plastic Floor Covering. Solvent-free adhesives based on acrylic and vinyl acetate – ethylene – acrylic emulsions are used for bonding vinyl, synthetic rubber, and polyolefin flooring. Solvent-containing contact adhesives (rubber- or polychloroprene-based) still are used for some applications (e.g., stairs). When water resistance is required, reactive polyurethane or epoxy resin adhesives are preferred to waterborne emulsions.

In addition to developing a certain minimum strength, the adhesives primarily have to meet demands on the dimensional stability of the covering.

Because of plasticizer migration between covering and adhesive joint, the adhesives for plastic floor coverings should be adjusted carefully in their composition. Plasticizers are commonly used for the production of coverings based on PVC.

Adhesives for Textile Floor Covering. The composition of waterborne adhesives for bonding wall-to-wall carpets is similar to that of linoleum adhesives. High initial tack (wet tack) and a resistance against carpet cleaners is required. Previously used solutions of poly(vinyl ethers) and rosin in mixtures of highly volatile solvents are still used for carpets that are extremely sensitive to water.

Conductive Adhesives. Conductive adhesives are available for bonding conductive floor coverings. The electrical properties are achieved by the addition of carbon fibers, carbon black, or graphite. Conductivity of a floor covering is sometimes required to avoid undesirable static charging.

Tile Adhesives. The thin-set process uses hydraulically hardening thin-set mortars based on cements, emulsion adhesives based on aqueous synthetic resin emulsions, which can be single-component ready to use tile adhesives or two-component adhesives consisting of modified aqueous emulsions and a cement-based compound, and reactive adhesives based on epoxy resins or polyurethanes.

Depending on the intended field of use, cement-based tile adhesives are modified with different amounts of redispersible synthetic resin powder such as co- or terpolymers based on vinyl acetate or acrylates. The recipe must be adjusted to the different types of tiles and natural stones. On account of the various types of tile adhesives corresponding standards may be found, for example in DIN, BSI, AFNOR (Association Française de Normalisation), UEAtc (Union Europeenne pour l'Agrement Technique dans la Construction) or as European Standards prepared by CEN.

9.12. Building Construction Adhesives

The use of adhesives in building construction imposed exacting requirements upon quality and

application techniques [92–98]. In addition to durability and resistance to mechanical stress, temperature and weather resistance are prime requirements. In prefabricated construction, the use of adhesives was an important requirement for efficient assembly techniques.

Adhesives as Additives for Hydraulic Compositions. Synthetic resin dispersions and redispersible synthetic resin powders that are added to cement-containing concrete mixes and mortars must be resistant to alkali and dilutable with water. Redispersible powders are added to cement-based adhesives in factory made mortars, while synthetic resin dispersions are mixed with the powder compound on the building site just before the adhesive is applied. The products that have been specifically developed for this purpose include, in particular, copolymers of vinyl acetate in combination with other esters or with ethylene and terpolymers of vinyl acetate, vinyl chloride, and vinyl laurate and also copolymers based on acrylates, methyl methacrylates and styrene, as well as styrene – butadiene. The additives modify the properties of the concrete. For example, they considerably improve the adherence of new concrete to old concrete. In addition, resistance to dynamic stress is considerably increased. The addition of anionic melamine resins is recommended also for establishing certain rheological properties. Adhesives based on cellulose ethers are added to cement-based systems and gypsum plasters to improve adhesion to the substrate and, by virtue of their hydrophilic character, retain water, thereby preventing mortars and plasters from drying out and improving their strength. Starch and starch ethers are used to modify the adhesion of cement mortars to mineral substrates.

Prefabricated Construction. Sandwich elements are widely used in prefabricated construction. In this case, bonding must meet stringent requirements with regard to stability and durability, especially in the case of exterior wall elements. Deflections attributable to differential temperature or moisture-induced expansion or contraction can amount to as much as 5 % of the length. The adhesive layer must be permeable to water vapor or act as a water barrier, depending on the structure and function of a given element. The adhesives used are two-component reactive resins, based mainly on epoxy resins, but polyurethane resins are used as well, as are elastomer-based contact adhesives that are applied on both sides.

With building components based on synthetic resin concrete (polymer concrete), the cement may be replaced partly or completely by organic binders, such as co- or terpolymeric vinyl acetates, acrylates or epoxy resins. Such systems are described as polymer cement (PC) if the cement as binder has been totally replaced with organic binders, and as polymer cement concrete (PCC) if the cement binder has been partly replaced by organic binders. These systems are mainly used to reface concrete surfaces.

Low-viscosity reactive resins are used to seal cracks in concrete constructions. These epoxy and polyurethane resins show excellent creepability and bond strength to concrete.

Assembly Adhesives. In carcass work, cement mortar is still widely used as a binder for mineral components. The disadvantages of cement mortar include its long curing time, its poor adhesion to old concrete, and its poor resistance to dynamic stress. For these reasons, adhesive mortars have been developed. They are mixtures of liquid, curable synthetic resins, such as epoxy resins or unsaturated polyester resins, blended with mineral additives, generally quartz, and the corresponding hardeners. They establish an excellent bond with hardened concrete, stone, metals, and certain plastics, and are used for applications involving particularly severe stress, for example, for cementing rail supports onto concrete sleepers, for fixing dowels and anchor bolts in concrete, for steel reinforcements, and for the permanent bonding of high-grade concrete elements.

For applications such as swimming pools and water-purification tanks, for which chemical resistance is required, or where resistance to dynamic stress is needed, special epoxy resins are used. Blends of a waterborne synthetic emulsion with a cement compound are suitable for applications with lower requirements. In some cases, e.g. sewage-treatment plants, elastomer-modified bitumen mortars are still used.

Another important application of reactive resins is the production of resin-bonded screeds that, by virtue of their high mechanical and chemical stability, are used, for example, for industrial floors. One particular problem is the

bonding of old concrete to new concrete, where peeling occurs because of the shrinkage of the new concrete layer. By applying intermediate layers of a suitable epoxy resin mortar, it is possible to establish permanent bonds with strengths greater than that of the concrete.

9.13. Adhesives for Bonding Textile Fabrics

Fabric bonding is a relatively new application for adhesives [99–103]. The particular demands that a fabric bond must satisfy make the replacement of conventional thread stitching very difficult:

Adequate bond strength
Resistance to washing and cleaning
No staining or discoloration
No spoiling of texture
Maintain breathability (in the case of spread adhesives)
Rapid setting

Adhesives are used widely in the apparel industry for applying interlinings. The interlinings or nonwovens are precoated with hot-melt adhesives. To maintain breathability, the adhesive is applied spot-wise rather than spread. Suitable adhesives for these and similar purposes are, for example, copolyamides of the 6,6/6,12 type and also boiling-resistant low-pressure polyethylene. 6,36/6,12/6-Terpolyamides based on dimeric acids are used because of their high flexibility, resistance to washing, and favorable application properties. Their softening range is generally from 100 to 150 °C. After cutting to size, the precoated interlining materials are fused using ironing presses (front fixing).

The introduction of other inexpensive thermoplastics into the fabric bonding field has met hitherto with little success. Polyesters, for example, are not sufficiently resistant to dry cleaning. By contrast, polyurethanes show high resistance and favorable bonding properties.

Another area in which adhesives are very widely used in the textile industry is the manufacture of chemically bonded nonwovens (→ Nonwoven Fabrics). The nonwovens are preformed by the dry-layer or wet-layer process and subsequently bonded by spraying or impregnation with adhesives. The binders used generally are products based on acrylates, synthetic rubber, and vinyl polymers. Nitrile and styrene – butadiene rubbers are used for industrial nonwovens because of the need for resistance to oils, fats, and organic solvents.

9.14. Flocking Adhesives

Flocking adhesives are used for bonding short (0.3 – 5 mm) monofilament textile fibers (known as flock or flock material) to a variety of substrates [104]. Compared to mechanical flocking processes, in which the flock is scattered or blown onto a layer of adhesive, electrostatic flocking has the greater importance. In electrostatic flocking, suitable finished fibers are oriented in an high-voltage electrical field and accelerated to such an extent that they penetrate deeply at one end into the open adhesive coating and are firmly anchored therein. The surplus, nonanchored flock is blown or brushed away after drying and setting of the adhesive.

Whereas flocking was formerly carried out for decorative reasons (imitation suede or velvet), technical and economic aspects (noise insulation, friction reduction) also have become significant. Major improvements in flocking adhesives undoubtedly have contributed to this situation. In addition to paperboard, woven fabrics, yarns, films, and wallpapers, plastics, plastic foams, metals, rubber profiles, glass bottles, and, occasionally, even interior walls and car bodies are being flocked to an increasing extent. The adhesives used for flocking primarily are emulsion-based adhesives, generally based on poly(vinyl acetate) or polyacrylates and their copolymers, in some cases with added cross-linking agents. However, solution adhesives (solutions of synthetic resins) and also solventless and solvent-containing reactive adhesives (epoxy and polyurethane adhesives) are also used.

The adhesives must satisfy various selection criteria, of which adhesion, strength, elasticity, and stability of the set adhesive film are the most important. In many cases, colored adhesives also are required. The adhesives generally are applied by spray guns or rolls. They must have sufficiently long open times and spread evenly on the substrate.

Because the adhesive represents the positive pole (earth) in the electrostatic flocking process, through which the charge must be dissipated rapidly, it is required to show a certain conductivity (maximum resistance $10^7\ \Omega$) This is not a problem where water-based adhesives are used, but in the case of solvent-containing adhesives, the necessary conductivity often can be obtained only by means of additives.

9.15. Adhesives for Bonding Glass

The bonding of mineral substrates generally requires high-polarity, low-shrinkage adhesives. These two requirements are satisfied by reactive adhesives [105–111]. In many cases, the bonding of glass additionally requires high transparency and UV stability of the adhesive for optical reasons. The adhesives primarily used are polar polymers such as epoxy resins and polymethacrylates in the form of two-component systems. For large-area compound bonding on an industrial scale, for example, for automobile windshields and bullet-proof glass, glass sheets are combined with laminates of poly(vinyl butyral) and plasticizer. The permeability of transparent glasses to radiation also allows the use of UV-hardening one-component systems based on methacrylates. Elastic glass-to-glass bonds and similar bonds between glass and other materials are obtained with rubber adhesives based on silicone and polysulfide.

The epoxy resins occupy a leading position as glass adhesives. Their hardening at room temperature can be varied over a wide range. Different curing systems are available for this purpose. Thermosetting epoxy resins that harden in a few minutes at 120 – 150 °C are used on industrial scale.

In certain cases, improvements in adhesion can be obtained by additionally priming the glass surface. The primers used are bifunctional products, for example, organosilanes. The adhesives used for bonding utility glass also are required to be resistant to boiling water. Organosilicon epoxy resins have proved to be effective for this purpose, and are used either on their own or in conjunction with conventional epoxy resin adhesives. In addition to their high resistance to water, siloxane – epoxy resin adhesives are of relatively high thermal stability.

9.16. Adhesives in Automobile Manufacture

Introduction. A variety of different adhesives, sealants, and coating compounds with a wide spectrum of properties, from high-strength structural adhesives with energy-absorbing properties (crash resistance) to highly elastic surface-coating compounds, are used in modern automobile manufacture. The boundary between adhesives and sealants is fluid and cannot be defined precisely. It is intended here to discuss only products that are applied for bondings and/or sealings between two parts or in gaps (e.g., in weld seams) which are able to transmit constructive strength, not for surface coating purposes, such as underbody protection.

Although the quantity in which the adhesives thus defined are used per vehicle depends largely on the model, the average value in Europe appears at present to be between about 8 and 12 kg.

For adhesives used in the body shop, strength and elasticity are tested from – 40 °C up to + 90 °C, whereas aging behavior is investigated under temperature load, in humidity, or in aerosols of salt solutions (salt spray test). There has been a steady increase in the use of alternating climate tests either with regular cycles between dry cold and humid heat (VDA) or with a single change from prolonged storage in humid heat to dry cold.

Because automobiles are manufactured in large numbers of up to a few thousand units per day, the adhesives must be formulated in regard to their processability such that they fit into the established production flow and its cycle time. In view of the increasing advance of automation and the use of robots for body assembly, ease of pumping through pipes, often of considerable length, and also appropriate rheology at the application stage are essential requirements. As far as possible, it is preferred to use one-component formulations with wash off resistance that are cured by the heat of the electrocoat, primer, and paint bake ovens. At the trim line, where no bake ovens are available, mainly one-component, moisture-curing or contact adhesives are used. Two-component products will acquire higher significance for bonding of plastics and for assuring rapid through cure. For new

production concepts, the cure speed of trim-shop adhesives will be very important.

Body and Paint Line. On the body line, all adhesives and sealants are applied to the steel surface covered with oil that is used for deep drawing and for corrosion protection. Accordingly, the adhesives and sealants used must be able to absorb the oil. In addition the adhesive must bond to a large number of surface coatings such as zinc, zinc – nickel, electrolytic zinc, fire zinc, prephosphated zinc, and organic coatings.

As hem-flange adhesive on hood and bonnet and on doors, high-strength adhesives are used in order to provide these components with the necessary inherent stability. High impact performance imparts improved crash resistance to the bonded parts and safety for the passenger cell. In addition, the adhesives afford effective protection against corrosion in these particularly sensitive areas (PVC plastisols, acrylics, epoxy resins). For further improving protection against corrosion and to obtain a cleaner appearance, the closed hem-flange seam is sealed with a sealing bead of PVC or acrylic plastisols; some automobile manufacturers are changing their sealing concept (clean paint shop), and these operations are allowed only in the body and/or trim shop. In the hem-flange seam, adhesives have largely replaced the hitherto customary spot welds.

For joining anti-flutter panels to the outer panels of bonnet and trunk, adhesives of relatively low strength and high elasticity are used both at the assembly stage and after electrocoating (PVC plastisols, rubber-based adhesives). These properties are necessary to insure that the bond seams do not "show up" on the outer surface (read-through effect). In this area, adhesive bonding has paved the way for constructions that cannot be obtained by other joining techniques. Rubber-based tapes or compounds are used for joining roof bows to roof panels.

For better protection against corrosion in spot-welded seams, the seams are treated additionally with an elastic adhesive/sealant (spot-weld sealer) based on rubber. Hot-and cold-application systems are in use.

Sealing tapes and/or sealing compounds (rubber-based, vulcanizing with different degrees of expansion or permanently plastic) are used for sealing in the region of fenders, wheel housings, sliding roofs, air louvers, tank supports, and roof linings. Die cut pieces (rubber-based) are used in some areas (e.g., door hinges, mirror mounts). Highly expandable (500 – 1000 %) rubber or EVA-based materials are used for sound absorption in cavities.

To give washing out resistance, pasty adhesives must be solidified by pregelling or precuring before they enter the cleaning process by passing them through a recirculating air oven, IR heaters, or induction heaters. Cleaning is followed by pretreatment (phosphating), electrocoat application, and oven baking at 180 °C. Various weld seams (drip rails, inner seams, outer seams) are later sealed with PVC or acrylic plastisols. The next step is the application of surface primer and final paint with the associated bake ovens.

Trim Line. In the trim shop, the fresh paint surface forms the substrate for a number of bonding operations in which parts prefabricated to a greater or less extent and subsupplied parts are adhesively bonded into the painted body. Because no more bake ovens are involved, cold-curing systems (moisture or two-component systems) are employed.

At the glazing stage (windshield, rear, and side windows), the insertion of a tacky sealing cord (rubber-based) into the elastomeric profile surrounding the glass panel provides for better sealing. In the last 20 years, there has been an steady increase in the use of direct glazing techniques in which a moisture-curing, one-pack polyurethane adhesive joins the glass panel to the painted body. Advantages include very effective sealing, the possibility of larger screens, and lighter body constructions (the glass panel now contributes to body rigidity via the modulus of the adhesive), and more creative freedom (lower air resistance). More recently adhesives for radio antennas integrated into the rear screen have been developed with high electrical resistance. Fast setting materials eliminate any fixing aids and guarantee short drive-away times.

Contact adhesives (polychloroprene, nitrile, or polyurethane rubber) are used for fitting vinyl roofs, roof linings, sound-deadening mats (where they are not already incorporated in the primer-coated body), and carpets. More recent prefabricated roof constructions are designed for bonding with special emulsions.

The waterproofing polyethylene film behind the door panel is sealed with pasty compounds or tapes (rubber-based). Folded lining films and hems on doors and carpets are sometimes secured with hot-melt adhesives (polyamide, polyethylene) because they set relatively quickly.

The mechanical spot fastening of the buffer strips around the body frequently is supported by the "underplacement" of a continuous tape, tacky on both sides (rubber based).

Subsupplied Parts. These parts are generally manufactured by subcontractors and are installed in the painted body in the course of trim line at the automobile assembly plant.

In the interior of the vehicle, prefabricated roofs consist of outer "decorative layers" that are bonded to the layers imparting mechanical rigidity (emulsions, contact adhesives, polyurethane hot-melt adhesives). Contact adhesives, polyurethane adhesives, and high-frequency welding auxiliaries (resin solutions or PVC-based emulsions) are used for attaching textiles or plastic films to the supports made of molded fiberboard or plastics for door inner panels. Emulsions, contact or polyurethane hot-melt adhesives are used for bonding textiles to molded fiberboard or plastics for parcel shelves.

On the exterior of the vehicles, rubber profiles around windows and doors and the trunk lid are "lap" bonded with cyanoacrylate adhesives because continuously extruded profiles cannot be used for sharp corners. To obtain effective sealing and better sliding in the case of sliding windows, these profiles are flocked by means of polyurethane-based flocking adhesives. The lenses of headlamps are joined to the housing by polyamide or polyurethane hot-melt adhesives and epoxy resins. The layers of laminated safety glass are bonded with a film based on poly(vinyl butyral).

Engine, Transmission, Chassis. In engines and transmission systems, components that must transmit torques, such as gear rims, are bonded with anaerobic adhesives (diacrylate based). The same group of products is used for thread locking. Gaskets formed in place in these areas consist of silicones or rubber – phenolic resin.

Rubber-to-metal bonding agents are used for the production of vibration-damping members of rubber and metal, developing their adhesion to the metal during vulcanization of the rubber. The same applies to the production of shaft seals. Clutch and brake linings are applied by means of nitrile rubber – phenolic resin adhesives.

In oil and air filters, the membranes are embedded in adhesives and/or fixed to metal frames (PVC plastisols, polyurethanes).

Future Trends. Short- and medium-term trends, such as the increasing use of plastic (sheet- or injection-molded compounds of glass-fiber-reinforced, unsaturated polyester resins, glass-fiber-reinforced polyurethanes, and polycarbonates) and lightweight alloys such as aluminum and magnesium will require new concepts for adhesives and sealants. New curing mechanisms are being sought to meet future production concepts (modular assembly). In addition the need to separate the multimaterial mix by disbonding processes for recycling and repair are special targets to be met by modern materials. Robots will guarantee further automation, lower baking temperatures will save energy, and the partial introduction of organic-coated steel panels for improved corrosion resistance will require slightly more versatility of the adhesives.

In the long term, materials for improved safety and comfort of vehicles of lightweight construction are required.

9.17. Adhesives in Aircraft Construction

The principle attractiveness of adhesive bonding in comparison to competing joining technologies (e.g., screws, riveting, brazing, welding) for the aircraft industry is mainly due to the following aspects:

High aerodynamic surface quality of bonded components due to smooth and precise contours

Superior properties with respect to stiffness, fatigue, and damage tolerance due to area-spreaded load transfer (no notches) with damping characteristics (vibration, sound)

Nearly universal and simple joining of different materials without any weakening (minimal thermal exposure/stresses, surface damage)

Simple realization of extremely lightweight sandwich and multilayer designs

Gas- and liquid-tight joints (no crevice corrosion)

All these advantages can be utilized for saving weight or increasing life expectancy. Also reductions in production cost may be realized.

Disadvantages are:

Strength properties are comparatively highly influenced by the environment (temperature, moisture, chemicals)
Some processes require relatively high production standards
Nondestructive testing is demanding and of limited significance
Technology-specific destruction mechanisms exist (delamination, bondline corrosion)

However, many of the risks combined with the application of bonding can already be eliminated by means of careful and experienced design.

The application of adhesives in early aircraft manufacturing was not very different from the general evolution of this joining technology. For example, variations in the stability of wooden constructions against moisture due to less suitable adhesives such as casein were experienced. However, impressive parts like the wooden wing of the pre-World War II Fokker F-36 airliner (33 m wing span) were bonded with no in-service problems reported.

The gathering of specific know-how in the aircraft industry started with the transition to metal structures made of aluminum. This step was first made during World War II in the United Kingdom in the light bomber "Hornet". In this aircraft some structural aluminum parts were adhesively bonded with newly developed thermosetting phenolic adhesives instead of the cold-setting acid-hardening urea – formaldehyde type formerly applied with wooden components. This two-component system, a liquid phenolic resin plasticized with poly(vinyl formal) powder, has to be cured at 155 to 175 °C and quickly found its way into civil aircrafts like the DeHavilland "Dove" and the first jet airliner "Comet" [189]. During investigations into the crash series of the latter model, the bonding technology was suspected to be the reason for catastrophic structural failures. The investigations ended with a complete rehabilitation of the bonds, and the adhesive is still in use in its original form or as a one-component precured (B-staged) film adhesive (e.g., skin panels of the Avro Regional Jet).

The most successful application example of this technology is the Fokker F 27/F50 "Friendship", in which about 70 % of the structure (ca. 550 parts) are bonded. The proven durability (> 1000 aircraft in service for up to 30 years) of this design is also due to the superior fatigue properties compared to a riveted construction. Additionally the chromic acid anodizing (CAA) of the aluminum surfaces before bonding resulted in corrosion-resistant joints.

Far less successful were further developments in the 1960s, when epoxy-based adhesives were introduced because of their higher temperature resistance and increased peel strength. Since no difference in mechanical properties were found between anodized and chromic sulfuric acid (CSA) etched aluminum, the advantage of low production costs was exploited. Delaminations of bonds after only two years in service and bondline corrosion events led to the recognition that the etch treatment produced an inconsistent oxide surface. Long-term salt-spray tests revealed the whole to be insufficiently stable to corrosive environments, especially as experienced in the bilge area of aircrafts. Expensive repairs and design modifications were the consequence.

The new standards then established [190], [191] included, besides the reintroduction of anodizing processes, careful edge protection, mandatory use of corrosion-inhibiting primer, and improved epoxy film adhesives with a curing temperature of at least 120 °C; this represents the technology mostly used up to today. Typical design rules require shear stresses of 10 MPa (static) and 1 MPa (dynamic). Any peel stresses should be avoided, but for safety purposes the bonds should bear about 4 N/mm in the floating roller peel test (e.g., EN 2243-2 [192]). In shear stress/shear strain tests (e.g., EN 2243-6 [193]) these adhesives show besides a nearly linear response up to at least 20 MPa and a failure strain of greater than 0.5.

Other lessons learned refer to the design of aluminum sandwich components consisting of a honeycomb core skinned with sheets. This extremely rigid and lightweight design is economically producible only by adhesive bonding, which also achieves superior stability against

sonic fatigue. Durability against corrosion can only be attained if the parts remain completely airtight in service or, in case of acoustic panels around the engine, which are regularly heat dried during service, are well ventilated by perforations with access to all cells. Preventive anodizing and priming with corrosion-inhibiting primers also of the core material has not been applied very often till today due to the higher material costs. Progress in the bonded-sandwich design of the acoustic panels has made a substantial contribution to reduction in noise emissions of jet engines in the last two decades.

Besides the chemical industry, the aircraft industry also pioneered the utilization of titanium alloys and developed adhesive bonding as an option for joining workpieces. Similar to aluminum, the pretreatment process is decisive for successful and durable bonding. Simple etching with fluorine-containing acids resulted in bonds which are highly prone to moisture intrusion by diffusion and adhesive failure. Alkaline etching processes are a better alternative, and most durable bonds are obtained with anodizing procedures [194], [195]. The reliability of adhesively bonded titanium is indicated by the fact that the joints between the titanium fuselage fittings and the carbon fiber reinforced plastic (CFRP) wing skins of the US fighter aircraft F18 "Hornet" are adhesively bonded.

To a certain extent the aircraft industry is returning to its roots by applying more and more fiber-reinforced plastics, starting with G(glass)FRP, going to A(aramid)FRP, and now mostly CFRP, because these materials possess some similarities to wood. For all FRPs the load-spreading properties of adhesively bonded joints is a key issue, and successful adhesive bonding requires careful surface conditioning. Mostly two processes are used: the peel ply technique and mechanical abrasion (sanding).

The peel ply technique integrates economical production of FRP parts with the advantage of obtaining reproducible surface conditions by using an outer woven ply (generally made of polyamide) during cure of the composite part. This ply, which is generally impregnated with an excess of the matrix resin of the composite part during the curing process, is removed (peeled off) just before the subsequent bonding process is started by applying the adhesive to the mating surfaces. A prerequisite for the successful application is that the peel plies are free of release agents and other contaminants.

More versatile are sanding processes. Especially the brushing of the surfaces with Scotchbrite pads and a slurry containing quartz particles and tensides cleans and prepares the substrates reliably. Prepregs can be directly bonded to such surfaces on cured laminates without using additional adhesive.

The workhorse adhesive materials for structural bonding in the aircraft industry are still the modified epoxy film adhesives curing at 120 °C or, for parts exposed to elevated temperatures (> 80 °C), 175 °C. Modification normally means the addition of other polymers that form a secondary phase of microscopic particles in the bondline and act as crack stoppers by distributing the stress of an advancing crack tip in the surrounding volume. For this purpose carboxy-terminated butyl nitrile (CTBN) rubbers are often used, but the addition of thermoplastics (e.g. polyamide, polysulfone) is also common. The epoxy resin itself is often made out of oxirane-terminated bisphenol A monomer and oligomer fractions. Additives are used to improve temperature and fire, smoke, toxicity (FST) properties. Curing agents are generally alkaline (amines, amides), often supported by accelerators, especially in the case of the adhesives curing at 120 °C.

Only for specific tasks with higher thermal stresses are polyimide-based adhesives utilized. Special products can withstand permanent in-service temperatures of 250 °C and more, but the application is economically often less attractive, so that such bonds are found mainly in military and aerospace components.

The most important room temperature (RT) curing two-component adhesives are also based on epoxy chemistry. These versatile materials are not only used for bonding, but also for other purposes like shimming, potting, encapsulation, and even impregnation of fibers and fabrics. Their domain is semistructural and interior joining. Because of early failures, their usage in structural applications (see above) has been restricted, but modern knowledge about failure mechanisms provides a basis for a return to the structural field. More recent developments have created materials with performance properties very similar to those of the tried-and-tested film adhesives. Especially the toughening properties

were improved, and maximum service temperatures generally range from 80 to 175 °C. Hence these materials are today a powerful tool for economical repair and maintenance tasks.

9.18. Adhesives and Sealants in Electronics

Introduction. The use of adhesives in the electronics industry is experiencing a period of rapid growth at the moment. Adhesives are increasingly expected to perform a variety of tasks in electronics assembly, including conducting or insulating electricity, conducting heat, sealing, and protecting, besides the more usual functions of mechanically fixing components and assemblies.

Conductive Adhesives.

Isotropically electrically conductive adhesives (ICAs) are widely used in the electronics industry when high-temperature soldering processes are unsuitable. Typical applications include silicon die attachment, component attachment in multi-chip modules (MCMs), surface mounted printed circuit board repair, and electromagnetic/radio frequency (EMI/RFI) shielding.

In all cases the conductive adhesive consists of high contents of conductive filler in an insulating polymer (adhesive) matrix. The choice of filler and adhesive matrix is dependent on the end use.

Die attachment adhesives are normally epoxy- or polyimide-based and contain 70 – 80 wt % silver flake. Silver flake is the common choice for conductive adhesives as the oxide layer formed on the flake is also conductive.

Polyimides became popular for die-bonding adhesives because they are cleaner (in terms of ionic contaminants) than equivalent epoxy products. The market, however, is dominated by high-purity epoxy adhesives. Polyimides are always applied from solvent solution and require higher curing temperatures than epoxies. They are stable to higher temperatures. Solvent-borne thermoplastics pastes (or cast-film preforms) have been used for some lower reliability die-attachment applications.

Epoxies form the basis of products in the multi-chip module (MCM) bonding and surface mount technology (SMT) repair areas. Two-pack room-temperature products (amine cure) are common in repair applications. Two-pack systems with acid anhydride curing are available as heat-cure products where a more robust final product is required. These two-pack systems are often pre-mixed by the vendor and supplied as a one-pack system requiring low-temperature storage. One-pack latent-heat-cure systems are also available based on dicyandiamide or imidazole adducts.

Electromagnetic/radio-frequency interference shielding materials have to meet much lower demands in terms of overall electrical conductivity (typically 4 – 5 orders of magnitude lower than a silver-flake-filled adhesive). This means that cheaper conductive fillers can be employed, for example, silver-coated copper flake, nickel flake, and carbon black. Typically the adhesive has to form a compliant joint between two mating surfaces, and hence room temperature vulcanizing or heat-cure silicone is often a convenient choice of matrix material.

Anisotropically conductive adhesives conduct in one direction only. They are often referred to as z-axis conductive adhesives. These materials have found widespread use in LCD assembly due to their ability to resolve small gaps between conductor tracks and the fact that solder is not suitable for joining on glass substrates.

The filler loading in anisotropically conductive adhesives is much lower than in conventional isotropic adhesives (typically 5 – 10 vol % as compared to >30 vol % for ICAs). The fillers consist of spherical particles that are often monodisperse; examples include gold-plated polymers, solid gold, silver, and nickel. The filler loading is carefully chosen to insure that the probability of short circuits between adjacent conductors is low but that there is high probability of conduction along the z-axis. The adhesive matrix is usually epoxy-based and the most common product form is B-stagable film. These films are cured for short times at high temperature (20 s at 180 °C) under pressure.

Thermally conductive adhesives are commonly used as an interface between heat sinks and heat sources (e.g., high-power semiconductor devices). Their function is to give a mechanical integrity to the bond between the heat sink

and heat source, but more importantly to eliminate air (which is a thermal insulator) from the interface area.

These adhesives consist of a polymerizable liquid matrix and large volume fractions of electrically insulating thermally conductive filler. Typical matrix materials are epoxies, silicones, urethanes, and acrylates, although solvent-based systems, hot-melt adhesives, and pressure-sensitive adhesive tapes are also available. Aluminum oxide, boron nitride, zinc oxide, and increasingly aluminum nitride are used as fillers for these types of adhesives. The filler loading can be as high as 70 – 80 wt %, and the fillers raise the thermal conductivity of the base matrix from $0.17 - 0.3\,\mathrm{W\,m^{-1}\,K^{-1}}$ up to about $2\,\mathrm{W\,m^{-1}\,K^{-1}}$.

Coating and Protection Products.

Conformal Coatings. A conformal coating is a thin polymeric layer applied to a printed circuit board (PCB) by brushing, dipping, or spraying as the last processing step. The coating provides a barrier which protects the PCB (conductors, solder joints and components) from environmental attack during service life of the product. Not all of the circuit board is coated; areas such as connectors, switches and relays are covered with tapes, rubber caps, or removable masks to prevent the conformal coating impairing their operation. Conformal coatings are available in a number of different formulations; these include polyurethane (solvent and nonsolvent versions), silicones, acrylates, acrylated urethanes, and epoxies.

The choice of coating depends on the chemical and mechanical (abrasion) resistance required, the degree of rework envisaged, and the method of curing. Polyurethane coatings have excellent humidity, chemical, and abrasion resistance. However rework can be difficult. Silicones give the greatest protection during thermal excursions but they are unsuitable where abrasion resistance is required. Epoxies provide excellent chemical and mechanical resistance, but the inherent mechanical stiffness of the coating can be detrimental to stress-sensitive components. Rework is difficult. Acrylated urethanes offer a combination of fast cure and excellent solvent resistance.

Parylene is a completely different class of coating. The *p*-xylylene monomer is stable as a gas at low pressure but polymerizes spontaneously on any surface on which it condenses. The polymer formed has excellent moisture, chemical, mechanical, and electrical properties, but expensive application equipment is required.

Encapsulants encompass a broad range of materials whose primary function is to protect electronic components from detrimental chemical, mechanical, electrical, or thermal environments.

Encapsulants are usually characterized as either potting compounds, glob-tops, or underfills, depending on the end use. Potting compounds are materials that are used to protect final assemblies (relays, component terminals, electrical contact assemblies, etc.). Glob-tops and underfills are specifically used for silicon die protection.

Three different potting compounds are commonly used: silicones (for low-temperature applications), polyurethane (for applications up to 120 °C) and epoxies (for general applications). Potting compounds should provide good adhesion to the assembly materials/substrates, low cure shrinkage (and hence low internal stress), and in large sections, low heat release on curing.

Glob-tops offer protection to silicon die wire-bonded directly onto a substrate (PCB, polyimide flexible circuitry or ceramic). The liquid encapsulant is designed to flow between the wire bonds to form a protective coating over the integrated circuit. In some cases the pitch between wire bonds necessitates the use of low-viscosity liquids, and in these cases a dam of compatible adhesive is first dispensed around the IC to prevent the glob top spreading to other areas of the PCB. Typically, glob tops will have low levels of ionic contaminants and low coefficient of thermal expansion (CTE). The CTE is an important consideration in all encapsulant applications; the primary requirement is that the CTE of the encapsulant closely matches that of the silicon die, substrate, and wire bonds to minimize stress in the joint (particularly under conditions of thermal cycling).

Underfills are a specific class of adhesives designed to protect silicon dies which are soldered active face down onto the PCB. In these flip-chip applications, the underfill material flows beneath the die by capillary action. These materials are generally highly loaded with inorganic fillers to reduce the coefficient of thermal expansion.

Anhydride-cured epoxies give the best combination of properties for most glob-top and underfill applications, in particular their high glass transition temperatures are desirable. Due to the need for single-component materials (for ease of handling and bubble-free packaging) the anhydride and epoxy are premixed. The resultant one-pack system is stored at $-40\,°C$ to give an acceptable product shelf life and a pot life of 8 h (or more) at room temperature. In some (lower reliability) glob-top applications UV curing acrylates or UV cationic epoxies have been used.

Surface Mounting Adhesives. Adhesives are commonly used to hold electronic components in position prior to wave soldering. One-component heat-curing epoxies are the most usual choice of surface mounting adhesive (SMA). These materials are thixotropic pastes based on bisphenol A or F type liquid epoxy resins and latent curing agents. The curing schedule of these materials is typically 3 min at 120 °C, with a six month (or longer) shelf life at 5 °C.

Acrylic SMAs form a smaller class of products. These materials are cured with both UV and heat, the UV curing mechanism insures rapid fixing, while the bulk of the adhesive (under the component) requires a heat-curing step. The shelf life of these products is long (12 months at ambient temperature) but overall product performance is inferior compared to the epoxy analogues.

Various adhesive application methods are available (dispensing, pin transfer and screen/stencil printing) and different adhesive rheologies are required in each case.

Adhesives for Liquid Crystal Display Manufacture. There are three main adhesive applications during the manufacture of a liquid crystal display (LCD): temporary plate fixing, main seal, and end seal. A number of LCD cells are made from single large flat glass plates. In the first process, the mainseal (or LCD gasket) is printed onto the glass to define individual cells, this is usually a solvent-borne epoxy. Once the solvent has been removed, a second glass plate is placed above the first and the mainseal is cured. To hold the two plates in the correct orientation while the mainseal is fully cured a temporary fixing adhesive is used. This is often a UV acrylic material. The final production step involves filling the cell with liquid crystal through a gap left in the mainseal and subsequently sealing the gap. This end-sealing operation is the only occasion when liquid adhesive comes into contact with the liquid crystal and hence the choice of adhesive is vitally important. Specially formulated UV acrylic formulations are most widely used for this application.

9.19. Medical Adhesives

Introduction. The use of adhesives in medical applications has a long history and may date back some 4000 years. Today, adhesives are used in a wide variety of surgical techniques albeit on a limited scale. The type of adhesive used depends on its application. It has to meet certain criteria with regard to its strength, toxicity, degradation pathway, and overall safety and efficacy. This applies equally to pressure-sensitive adhesives used in simple wound dressings to more advanced sealants that are used to plug small holes in blood vessels following cardiovascular surgery. Almost all branches of medicine have experimented with the use of adhesive to replace or augment traditional techniques. This section briefly reviews some of the more commonly used adhesives in medical and dental applications.

Tissue Bonding and Wound Sealing. Skin acts as a barrier to infection and dehydration. When it is breached in the form of a cut it is desirable to have it sealed quickly and effectively. Cyanoacrylates (CAs) have been developed as an alternative to the standard method of suturing (stitching) a wound [196]. CAs have the advantage over sutures that complete tissue closure can be effected, thereby preventing further fluid loss. Normally higher ester forms of CAs such as butyl are used. These result in less tissue inflammation than the methyl and ethyl esters, possibly due to slower degradation. As the polymerization process is exothermic, care must be taken to ensure that the setting speed is not too rapid, otherwise thermal damage to the surrounding tissue may occur. This is circumvented by using very small amounts of the adhesive and by using higher esters. The rate of polymerization

is related to the size of the ester alkyl group. Generally, the larger the alkyl group, the longer the setting time, and hence there is more time for the heat generated to dissipate. Sterilization of CAs can be problematic since it often results in premature polymerization. Sterilization of CAs by dry heat and by gamma irradiation has been described in the literature.

Trade Names.Indermil, Loctite Corporation and Histoacryl, B. Braun, Aesculap, B.B.D. (based on cyanacrylic butyl ester); Dermabond, Closure Medical Corporation (based on cyanacrylic octyl ester).

Fibrin [197] is the body's natural glue or sealant and is produced in response to injury and bleeding. It helps form a clot, thereby sealing damaged blood vessels. Fibrin is formed by the cleavage of fibrinogen (a larger, soluble, blood-based protein) by the enzyme thrombin. This causes a structural modification resulting in the precipitation of fibrin to form a fine mesh which traps escaping blood cells. Fibrin acts well as a sealant and as a hemostatic agent, buts lacks the bond strength of synthetic chemical adhesives such as CAs. The individual components involved in this process can be purified from blood and be used in a variety of medical applications. It is especially useful in cardiovascular surgery.

Although they have quite different properties CAs and fibrin have been used for the same application. For example, both have been used to attach skin grafts to wound sites; to control bleeding and promote hemostasis; in vascular and intestinal anastomoses; and in ophthalmic surgery. Fibrin, being naturally derived, is more biocompatible. However, it is derived from blood and there is concern about transmission of pathogens. Fibrin(ogen) can be sterilized by a combination of either solvent/detergent or heat treatment to inactivate viruses, followed by ultrafiltration.

Trade Names.Tisseel, Immuno AG; Beriplast, Beringwerke.

Adhesives for Protective Dressings and Related Applications. Pressure-sensitive adhesives (PSAs) serve many applications in this area. Acrylates are the preferred elastomeric components of PSAs for general dressings. Acrylic hot-melt PSAs are useful for nonwoven web carriers due to their limited penetration. Specially chosen PSA formulations are used where allergic skin reactions are known or likely. Silicone-based PSAs may also be used in sensitive applications such as the attachment of prostheses and monitoring equipment probes. PSAs are also used to attach drug-delivery systems to the human body. Where the PSA forms a layer between the delivery source and the body tissue, particular care is needed to ensure adhesive function while facilitating drug availability. The design of such products depends largely on the size of the drug molecule.

Orthopedic Adhesives/Bone Cements. Acrylic bone cements [198] are the only group of materials used to anchor long-term implantable devices to the neighboring bone. Though the bone cements have drawbacks, including trauma created by a highly exothermic hardening process, over 90 % of hip and knee repairs function well for 15 years. The bone cements consist of separate powder and liquid components which are mixed carefully prior to application.

Though many products exist, the powder component always contains methacrylate polymer, a polymerization initiator, and a radiopaque medium. The liquid component contains methyl methacrylate with small amounts of accelerator for the hardening process. Hand mixing may be used. However, many proprietary mixing devices exist to give optimal properties and reproducibility.

Trade Names.Simplex, Howmedica; Palacos, Zimmer.

Dental Adhesives. Adhesive technology, cements and composites have added greatly to restorative dental surgery. Restoration of teeth with dental fillings is now often carried out with resin-based composites. These consist essentially of an organic methacrylate functional resin matrix, inorganic fillers, and coupling agents. Successive products have enhanced properties, in terms of the curing process, ease of use, and wear resistance. Light-curing systems are now popular since they allow relatively unlimited working time followed by rapid hardening when exposed to light of the appropriate wavelength. The bonding of crown materials is usually done with similar compositions, though here systems which cure by mixing reactants are necessary since light only reaches peripheral areas.

Glass – ionomer cements have taken a major place in dental treatments as restorative filling materials and also in a range of more adhesive applications due to their ability to bond to both dentine and composite fillers. Acid-etching techniques are well established for the bonding of resins to enamel.
Trade Names.P 100 (Composite Dental Adhesive), 3M; Dyract (Glass Ionomer Cements), Dentsply.

9.20. Household Adhesives

Household adhesives are used for gluing, assembling, or repairing a variety of materials in the household. They include a large number of different adhesive types, usually offered in smaller packages such as tubes, bottles, or tins.

The following list provides a survey of adhesive types frequently used in households:

Paper adhesives in solid (glue sticks), liquid, or cassette form (adhesive rollers)
Multipurpose adhesives
Adhesive tapes and pads
Cyanocrylate adhesives
Hot-melt adhesives
Two-component adhesives
Contact cements
Plastic adhesives
Wood glues
Assembly adhesives

The term do-it-yourself adhesives has also become generally accepted besides the term household adhesives. A clear differentiation between the two ranges of adhesives is not possible. The above-mentioned household adhesives also include DIY adhesives. In addition to the above applications, DIY adhesives are also used for light renovation work in and around the house and are therefore also offered in larger packages or for activities such as wallpaper hanging. They include:

Building chemicals such as tile adhesives, joint mortars, fillers, leveling compounds, and plasters
Wallpaper pastes
Flooring adhesives
Sealants
Polyurethane foams

Glue Sticks (Paper Adhesives, Solid). Glue sticks are used for gluing paper, cardboard, photos, and labels. Most of these sticks are solvent-free and contain a soap gel as builder and natural and/or synthetic polymers as adhesive component. They are also marketed as refillable sticks.

Of late, higher performance glue sticks based, for example, on polyurethane, which can be used to glue other materials such as wood, plastics, and metals have become available.
Trade Names.Pritt Stick (Henkel, Germany); UHU Stic (UHU, Germany); Tesa Klebestift (Beiersdorf, Germany); Fueki Stick (Fueki, Japan); Glue Stic (Avery Division, USA); Glue Stic (Grand & Toy, Canada); Kores Glue Stic (Kores, India); Glue Stick (Scotch 3M, France).

Paper Adhesives, Liquid. Liquid paper adhesives are used in the household for gluing paper and cardboard. These mostly solvent-free adhesives are partly based on natural raw materials such as dextrin, starch, and cellulose derivatives (pastes). They are sold in bottles and tubes but also as pens.
Trade Names.Pritt Pen (Henkel, Germany); UHU klebefix (UHU, Germany).

Adhesive Rollers (Paper Adhesives in Cassette Form). Adhesive rollers are newly developed adhesive systems for gluing paper, cardboard, and photos. The adhesive film is applied to a paper or foil carrier which is rolled up and placed in a cassette, usually with automatic take-up. This adhesive film is then rolled onto the parts to be glued on a solid surface. Adhesive rollers have the advantage over conventional paper adhesives that no drying time needs to be allowed after application of the solvent- and water-free adhesive film. Adhesive rollers are offered in various sizes, sometimes with refill cassettes. They are available for permanent and nonpermanent applications.
Trade Names.Pritt Roller (Henkel, Germany); Uhu multi roller (Uhu, Germany); Tombow (Japan).

Multipurpose adhesives are very versatile and can be used to bond most materials such as cardboard, paper, felt, textiles, wood, metal, glass, and plastics. They are also used for small-scale assembly or as a handicraft adhesive. Depending on the material, the bonding strengths

achieved are different and in most cases on a medium level.

The solvent-free multipurpose adhesives contain transparent to opaque dispersions or solutions based on polyurethane or acrylate. In addition, white dispersions based on poly(vinyl acetate) or acrylate (so-called white glues) are available for all-purpose applications. The solvent-containing types mostly consist of poly(vinyl acetate), vinyl acetate copolymers, or nitrocellulose, dissolved in a solvent mixture of esters, ketones, and alcohols.

Trade Names.Pattex Haushaltskleber transparent (Henkel, Germany); Pritt Alleskleber (Henkel, Germany); Uhu flinke Flasche (Uhu, Germany); Tesa Vielzweckkleber (Beiersdorf, Germany); Elmer's school glue (Borden, USA).

Adhesive Tapes and Pads. Adhesive tapes make use of foils, paper, or fabric as a carrier material which is coated with a permanently sticky film. In the household these tapes, which can be bought in different types and sizes (one-sided or two-sided adhesive tape), are primarily used for packaging, for small-scale assembly, and for masking when doing renovation work.

By contrast, two-sided adhesive pads consist of foamed carrier materials or extruded caoutchouc pastes and are used to fix lightweight objects on to smooth, level surfaces.

Adhesive pads for easily removable bonds that do not require a carrier material and are particularly suited for fixing posters, graphics, and other lightweight objects, even to sensitive substrates such as wallpaper.

Trade Names.Pritt Klebepads (Henkel, Germany); Tesa Klebebänder (Beiersdorf, Germany); Tesa Power Strips (Beiersdorf, Germany); Duck Tapes (Manco, USA); Scotch (3M, USA).

Cyanoacrylate adhesives are used in households for repair work. As these adhesives cure very fast and hardly bridge larger cracks, they are only suitable for small, snug fitting parts. Cyanoacrylate adhesives can be used to bond almost any material, both porous and smooth.

The main ingredient of this adhesive is a cyanoacrylic acid ester (methyl, ethyl, or butyl). Special esters such as methoxyethyl esters are employed for the odorless types. Cyanoacrylate adhesives are mainly available in small aluminum tubes or plastic bottles at different viscosities ranging from highly liquid to gel-like.

Trade Names.Pattex Blitz-Kleber (Henkel, Germany); Super Attak (Loctite, USA); Uhu Sekundenkleber (Uhu, Germany); Krazy Glue (Toagosei, Japan); Aron Alpha (Toagosei, Japan); Cyanolit (3M, USA).

Hot-melt Adhesives. In household applications, hot-melt adhesives are used in cartridges together with the necessary gluing pistols. They are suited for repair and small-scale assembly work, being able to bond almost any material. The special advantage of hot-melt adhesives is that the bonded parts already can be subjected to stress or further processed after a few minutes. A certain drawback is their high processing temperature of ca. 200 °C, which renders the bonding of temperature-sensitive materials such as styrofoam or plasticized PVC more difficult. Lately, so-called low-melt cartridges have come in use which can be processed at a temperature as low as ca. 110 °C. Furthermore, mini-pistols are offered which accommodate smaller cartridges, colored cartridges, or cartridges with a glitter effect.

Those hot-melts that find application in the household and DIY applications are usually based on ethylene – vinyl acetate copolymers (EVA) and contain tackifying resins (e.g. hydrocarbon resins). Today's pistols are equipped almost without exception with a mechanical feed, differ in their heating power, and are partly designed for cordless work.

Trade Names.Pattex Patronen (Henkel, Germany); Uhu Klebepatronen (Uhu, Germany).

Two-component adhesives that are used for household applications differ quite strongly as to their properties. For instance, there are epoxy resin adhesives that are very well suited for bonding glass, china, ceramics and metals. They dry glass-clear, are dishwasher-safe, and therefore exceptionally well suited for repairing dishes or similar household articles. Usually, the two components resin (epoxy) and hardener (amine or mercaptan) are filled in aluminum tubes or plastic double syringes and are mixed before application according to the directions for use. Other two-component adhesives are based on methacrylate and contain a powder hardener (dibenzoyl peroxide in gypsum).

These adhesives bond materials such as stone, plastics, ceramics, and metal; they achieve very high strength and bridge cracks and are therefore well suited for repair and small-scale assembly work.

Further two-component adhesives are available based on polyurethane; here, the resin component contains a polyol (filled or unfilled) and the hardener component a polyisocyanate. These adhesives, too, are suitable for bonding metal, plastics, ceramics, and wood. Special highly filled types can be used both for bonding and as a filler; after curing they can be processed like wood.

Two-component adhesives are used in the household when more difficult materials such as metals, glass, or certain plastics are to be bonded, when high strength is required, or when larger gaps must be bridged.
Trade Names.Pattex Stabilit Express (Henkel, Germany); Pattex Kraft-Mix (Henkel, Germany); Uhu plus (Uhu, Germany); Scotch Weld (3M, USA); Bond E (Japan).

Contact Cements. In the household, contact adhesives are used in many areas for gluing and repairing. They are mainly used when larger and heterogeneous items (e.g., wooden materials with decorative laminates) are to be joined, when difficult parts (e.g., veneer strips on the curves and edges of furniture) are to be fixed, or when flexible materials such as rubber or leather (e.g., shoe repair) must be bonded or repaired. Furthermore, contact adhesives can be used to bond materials such as cork, felt, plastics, soft foams, and metals.

Most contact adhesives contain a solvent and have a formulation that combines a base of synthetic rubber such as polychloroprene or polystyrene – butadiene with reactive phenolic resins and metal oxides. In addition, there are also transparent types based on polyurethane which provide excellent bonding results for soft plastics such as plasticized PVC (used in many household articles). A solvent-free generation of contact adhesives, e.g., based on acrylate, has entered the market. This type can be used to bond solvent-sensitive materials such as polystyrene foam.

Contact adhesives are sold either in cans or tubes with different viscosities (liquid or gel-like). Their application differs from that of other adhesive systems in a few points. The adhesive is applied to both parts to be joined, after which the solvent or water is allowed to evaporate (5 – 40 min, depending on the adhesive). After the evaporation time, bonding is possible within a defined period (open time) by pressing both parts briefly but with the highest possible pressure together.
Trade Names.Pattex Kontaktkleber (Henkel, Germany); Uhu greenit (Uhu, Germany); Elmer's (Borden, USA), Cemendine (Japan).

Plastic adhesives are used in the household or for model-making. They are able to bond nearly all plastics, for example, polystyrene, ABS, plexiglass, polycarbonate, and rigid PVC. Plastic adhesives partly belong to the solvent-welding adhesives. As they contain solvents such as butyl acetate, the surface to be bonded is slightly solvated, and this results in a solvent-welding effect. Plastic adhesives are mostly offered in small bottles, partly equipped with fine-dosing nozzles.
Trade Names.Pattex Plastic (Henkel, Germany); Uhu Plast (Uhu, Germany).

Wood glues are generally ready-for-use, water-based white glues based on poly(vinyl acetate). In the household they are used for assembling or for repairing wooden materials. After applying the glue, the wooden parts to be joined must be cold- or hot-pressed for a certain amount of time. In addition to the conventional wood glues, the market offers special fast-curing and waterproof types, also based on reactive polyurethane.
Trade Names.Ponal Holzleime (Henkel, Germany); Uhu coll (Uhu, Germany); Dorus Holzleim (Dorus, Germany); Elmer's wood glue (Borden, USA), Rakoll (Fuller, USA).

Assembly adhesives are relatively new adhesive systems which also find application in households. Assembly adhesives are able to produce very high bonding strength and high initial tack so that the parts to be joined need not be fixed. They are used whenever the powerful fastening of mostly different materials is required (both small and large areas), i.e., in cases where nailing, screwing and drilling were necessary up to now.

Typical applications include for example the bonding of wooden panels, skirting boards, decorative and insulating panels, plasterboards, tiles, etc. Moreover, it is also possible to bond difficult parts such as mirrors onto absorbent or nonabsorbent substrates, styrofoam sheets on metal, or nonferrous metals.

Assembly adhesives are either available as dispersions or as one-component reaction adhesives in cartridges or tubes.

Trade Names.Pattex Montageklebstoffe (Henkel, Germany); Mastic colle neoprene (Rubson, France); One for all (Bison, The Netherlands); PU-Fixkleber (Compacta, Germany); Sikaflex 221 (Sika, Switzerland); Montagekleber MK (Fischer, Germany); Fix all (Soudal, Benelux); Draft basters (Manco, USA); Multifix (Quilosa, Spain).

9.21. Applications of Anaerobic Adhesives.

Applications of anaerobic adhesives [199] are as follows:

Thread locking: The first applications for anaerobic adhesives were for locking threaded fasteners against vibration. Filling the "inner space" between a nut and bolt with a hard, dense material prevents self-loosening [200].

Thread sealing: The effect of filling the space between threaded parts or the space between inner and outer pipe threads provides a seal which can prevent the leakage of oil and other fluids in machinery as well as prevent corrosion of the threaded parts.

Retaining: Cylindrical press-fits and bearing assemblies can be retained with anaerobic adhesives, allowing accurate alignment and relaxed tolerances. Retaining and sealing of cup plugs and oil seals in castings is a major application.

Impregnation: Powdered metal parts, porous castings, and welds can be sealed against leakage of liquids or gases. This impregnation can also allow such parts to be plated and improves their machinability.

Preapplied Films: Thread lockers and sealants can be coated on threaded parts in the form of a dry-to-the-touch film. These preapplied materials remain inert until assembly releases a quick curing resin or an initiator.

Gasketing: Anaerobic flange sealants can be applied manually or by automated methods such as tracing, stenciling, and screen printing. These products can replace a variety of preformed, precut gaskets, and they can also be used as a gasket dressings.

Structural Bonding: Tough structural bonds can be achieved with some anaerobic adhesives for bonding components such as ferrite magnets, honing stones, identification tags, and decorative inserts.

10. Economic Aspects

More than 1500 adhesives manufacturers worldwide offer a variety of not less than 250 000 products. The worldwide turnover of the adhesives industry is believed to be approximately $\$16 \times 10^9$ corresponding to a total consumption of 6×10^6 t. These figures do not include cement-based products and urea and phenolic resins used a binders for the production of chipboard. Market studies and national industry federation reports are available for the United States, Canada and Mexico, Latin America, western Europe, eastern Europe, Asia/Pacific, Japan, and Australia. The regional distribution of the world adhesives market is given in Table 1.

Table 1. Regional distribution of the world adhesives market

Region	10^6 \$	1000 t
Canada and Mexico	413	187
United States	5799	2277
South America	302	130
Western Europe	3733	1470
Eastern Europe	887	323
Middle East	314	114
Africa	230	86
Asia/Pacific	1882	654
Japan	1925	585
Australia, New Zealand, Oceania	175	65
World total	15 660	5891

Adhesives have a very wide spectrum of applications. They are applied in almost every industrial field. The largest markets are found in the paper, packaging, and board industry (35 %), the building, construction, civil engineering and

craftsmen industry (28 %), and the woodworking industry (15 %). The forecasts for the future growth rates vary. The highest growth rates are expected in the automotive industry and the packaging and the converting sectors.

Considering the product groups, the highest growth rates are expected for hot-melt systems and polymer dispersions and emulsions. A continuing decrease will occur for adhesives based on natural polymers (animal and vegetable), solvent-based adhesives, and systems based on water-soluble polymers.

1. Introduction

Adipic acid, hexanedioic acid, 1,4-butanedicarboxylic acid, $C_6H_{10}O_4$, M_r 146.14, $HOOCCH_2CH_2CH_2CH_2COOH$ [*124-04-9*], is the most commercially important aliphatic dicarboxylic acid. It appears only sparingly in nature but is manufactured worldwide on a large scale. Its primary application is in the production of nylon 66 polyamide, discovered in the early 1930s by W. H. Carothers of DuPont. Manufacture of nylon 66 polyamide fiber has grown to become one of the dominant processes in the synthetic fiber industry. The historical development of adipic acid was reviewed in 1977 [5].

2. Physical Properties [6]

Adipic acid is isolated as colorless, odorless crystals having an acidic taste. It is very soluble in methanol and ethanol, soluble in water and acetone, and very slightly soluble in cyclohexane and benzene. Adipic acid crystallizes as monoclinic prisms from water, ethyl acetate, or acetone/petroleum ether. Some physical properties of adipic acid follow:

mp, °C	152.1
bp, °C	
at 101.3 kPa	337.5
at 13.3 kPa	265
at 2.67 kPa	222
at 0.67 kPa	191
at 0.133 kPa	159.5
Relative density (170 °C)	1.085
Bulk density, kg/m^3	600 – 700
Solubility, g/100 g water	
at 15 °C	1.42
at 40 °C	4.5
at 60 °C	18.2
at 80 °C	73
at 100 °C	290

3. Chemical Properties

Adipic acid is stable in air under most conditions, but heating of the molten acid above 230 – 250 °C results in some decarboxylation to give cyclopentanone [*120-92-3*], *bp* 131 °C. The reaction is markedly catalyzed by salts of metals, including iron, calcium [7], and barium [8]. The tendency of adipic acid to form a cyclic anhydride by loss of water is much less pronounced compared to glutaric or succinic acids [9].

Adipic acid readily reacts at one or both carboxylic acid groups to form salts, esters, amides, nitriles, etc. (Chap. 8). The acid is quite stable to most oxidizing agents, as evidenced by its production in nitric acid. However, nitric acid will attack adipic acid autocatalytically above 180 °C, producing carbon dioxide, water, and nitrogen oxides.

4. Production

Early commercial processes for manufacturing adipic acid involved a two-step air oxidation of cyclohexane [*110-82-7*]. Oxidation of cyclohexane to cyclohexanol – cyclohexanone at low conversion was followed by a high-conversion process for air oxidation of the mixture to adipic acid. Currently (2000), however, all large-scale production is via nitric acid oxidation of cyclohexanol [*108-93-0*], cyclohexanone [*108-94-1*], or a mixture of the two [ketone – alcohol (KA) oil].

Differences among commercial processes are mainly in the manufacture of the KA oil. The six carbon atoms of the adipic acid backbone usually come from benzene, which is hydrogenated to cyclohexane, or phenol, which is hydrogenated to cyclohexanol. The cyclohexane is then oxidized with air to KA oil. In the past 20 years, there has been a shift to the lower cost cyclohexane-based process [10]. (For KA production, see → Cyclohexanol and Cyclohexanone).

Since the early 1980s, a great deal of research has been carried out on the synthesis of adipic acid from butadiene and carbon monoxide (Section 4.3). However, no commercial plant based on this technology is currently in operation.

4.1. Nitric Acid Oxidation of Cyclohexanol

Reaction Mechanism. The second step of the conventional process, developed by DuPont in the late 1940s, involves the oxidation of cyclohexanol, cyclohexanone, or a mixture of both with nitric acid [11], [12]. Adipic acid is obtained in greater than 90 % yield. Major byproducts are carbon dioxide, nitrogen oxides, and some lower molecular mass dicarboxylic acids. Some byproducts arising from impurities in the starting KA oil are also present.

The chemical mechanism was discussed originally in 1956 [13] and later in greater detail [14], [15]. The latter reports include kinetic and reactor design considerations. Results of related studies, especially on the later stages of the reaction, were published at about the same time [16–18]. A summary of the findings of these investigations is given in Figure 1.

Cyclohexanol (**1**) is oxidized to cyclohexanone (**2**), accompanied by generation of nitrous acid. The cyclohexanone then reacts by one of three possible pathways leading to the formation of adipic acid (**8**). The major fraction of the reaction occurs via nitrosation to produce 2-nitrosocyclohexanone (**3**), then by further reaction with nitric acid to form the 2-nitro-2-nitrosoketone (**6**). Hydrolytic cleavage of this intermediate gives 6-nitro-6-hydroximinohexanoic acid, also known as nitrolic acid (**9**). This breaks down further to give adipic acid and nitrous oxide, the main unrecovered nitric acid reduction products. Typically 2.0 mol of nitric acid is converted to nitrous oxide for each mole of adipic acid produced.

The second pathway occurs at higher temperature, where nitration predominates. At these elevated temperatures, the pathway via the dinitroketone (**4**) becomes significant.

The third path proposed by the early investigators involves the intermediate formation of the 1,2-diketone (**5**) or its dimer. Conversion of this material to adipic acid in good yield requires the use of a vanadium catalyst. The effect of vanadium on the overall yield suggests a significant contribution by this pathway.

The intermediate nitrosoketone (**3**) can undergo two important side reactions. Multiple nitrosation leads to the intermediate (**10**), which loses carbon dioxide to produce glutaric acid

Figure 1. Reaction paths in nitric acid oxidation of cyclohexanol

(**11**) or succinic acid from subsequent reaction with nitric acid. Copper metal is added to the nitric acid to inhibit these reactions. In systems containing a relatively high steady-state concentration of the nitrosoketone (**3**) or the tautomeric oximinoketone, a Beckmann-type rearrangement leads to 5-cyanopentanoic acid (**12**) in minor amounts. This material is slowly hydrolyzed to adipic acid.

Commercial Nitric Acid Oxidation Processes. The basic technology for carrying out the nitric acid oxidation of cyclohexanol – cyclohexanone (KA) remains similar to that described in the early patent literature. Advances have centered on improvement in byproduct removal, catalyst and nitric acid recovery, and suppression of nitrous oxide, a greenhouse gas which was traditionally vented to the atmosphere. Because of the corrosive nature of nitric acid, plants are constructed of stainless steel (type 304L or better), or of titanium in areas of most severe exposure. The block flow diagram in Figure 2 shows a typical layout for a commercial nitric oxidation process [5], [19]. The reaction is carried out in a continuously circulated loop of nitric acid mother liquor (NML) that passes through the entire system, as shown by the bold line.

Figure 2. Flow diagram of a process for nitric acid oxidation of cyclohexanone – cyclohexanol
a) Reactor; b) Cleanup reactor; c) NO_x bleacher; d) Nitric acid absorber; e) Concentrator; f) Crystallizer; g) Filter or centrifuge; h) Dryer; i) Cooler

The reactor (a) is essentially a large heat exchanger, controlled at 60 – 80 °C and

0.1 – 0.4 MPa. To this is fed the recycled NML, the KA feed material, the makeup acid containing 50 – 60 % nitric acid and the copper – vanadium catalyst [20], [21]. Residence time in (a) is less than 5 min. In some facilities, the effluent is passed through a second reactor (b) at elevated temperature (110 – 120 °C) [22]. This high-temperature converter (b) can be used to complete the reaction and reduce the amount of impurities which need to be removed through crystallization. The reaction is very exothermic (6280 kJ/kg) and normal heat-exchanger surfaces tend to frost, leading to loss of temperature control. Several different reactor designs have been patented which aid in removing the heat of reaction and minimizing energy usage in the process [23–28]. An excess of recycled NML to KA feed stream of at least 3 : 1 and up to 1000 : 1 is maintained to control the reaction and improve the yield [21].

The product stream is passed through a bleacher (c), in which excess dissolved nitrogen oxides are removed with air and sent to the absorber (d), where they are reabsorbed and recovered as nitric acid. The off-gas from the absorber can be used to initiate the oxidation at lower temperatures by passing it through the KA feed stream before it is fed to the oxidizer [29–31]. Removal of the NO_x from the off-gas by scrubbing with KA has also been described [32]. The water produced in the process is then removed in a concentrating still (e) that is usually operated under vacuum. The concentrated product stream is either recycled to the reactor with diversion of a portion to product recovery or passed to product recovery prior to recycle of the NML filtrate. Crude adipic acid is removed from the NML loop by crystallization (f) followed by subsequent filtration or centrifugation (g) [33–35]. A portion of this effluent stream, which contains high concentrations of glutaric acid, succinic acid, and byproducts, is processed to recover the vanadium and copper catalysts and remove the byproduct acids. Metal recovery is usually accomplished by ion exchange [36]. The crude adipic acid from the first crystallizer (g) is dissolved and recrystallized at least one additional time before proceeding to a dryer (h) and a cooler (i). If the adipic acid is not needed in dry form, the crystals from the centrifuge/filter (g) can be dissolved in water and added to a solution of aqueous 1,6-hexanediamine to make nylon salt.

Other improvements of the conventional process have been described [37], especially in connection with separation and recovery of the dibasic acid byproducts [38–41]. The crude adipic acid is refined to varying degrees, depending upon the end use, but usually is recrystallized from water. Destruction of impurities by refluxing in 60 % nitric acid containing dissolved vanadium has been claimed to produce high-quality product [42].

4.2. Butadiene-Based Routes

In the early 1970s, BASF began an extensive research program on producing dimethyl adipate, a diester that could be hydrolyzed to adipic acid. The process involved carbomethoxylation of butadiene with carbon monoxide and methanol to give methyl 3-pentenoate using a cobalt catalyst and pyridine at high-pressure [43]. The methyl 3-pentenoate was then separated from byproducts by distillation. The second carbomethoxylation to give dimethyl adipate occurs at lower pressure but requires a lower pyridine to cobalt ratio [44]. The hydrolysis of the diester to adipic acid and methanol is a high-yield catalytic process [45]. The overall yield from butadiene appears to be about 70 %. It is believed this process has been demonstrated on a pilot-plant scale, but not yet commercialized.

In the mid-1980s, DuPont also began a major program on a butadiene-based route. In contrast to the BASF diester route, it involved the direct dihydrocarboxylation of butadiene to adipic acid (Fig. 3). The first step [46], which can be catalyzed by palladium, rhodium, or iridium, leads to largely 3-pentenoic acid (**12**). The second step [47], catalyzed by rhodium or iridium gives adipic acid (**13**), 2-methylglutaric acid (**14**), and 2-ethylsuccinic acid (**15**). The advantage of this process was that the 2-methylglutaric and 2-ethylsuccinic acids could be isomerized to adipic acid by the same catalyst system [48]. The catalyst seems to require a halide promoter, such as hydroiodic acid. The solvent for this process is usually a saturated carboxylic acid, such as pentanoic acid, which is a byproduct of the process. Since the late 1980s most major chemical com-

panies have issued numerous patents on variations of these butadiene based routes [49–51].

Figure 3. Hydrocarboxylation of butadiene to adipic acid

4.3. Other Routes

In addition to the commercial two-step air/nitric acid oxidation of cyclohexane and the carboxylation/carbomethoxylation of butadiene, several other processes have been investigated. Research at Monsanto on palladium halide catalyzed dicarbonylation of 1,4-disubstituted 2-butenes was reported in early 1984 [52]. This process produces adipic acid from 1,4-dimethoxy-2-butene, carbon monoxide, and palladium chloride at 100 °C after the resulting unsaturated dimethyl ester has been hydrogenated and hydrolyzed.

The one-step oxidation of cyclohexane with nitric acid [53], [54], nitrogen dioxide [55], or air has been described. The one-step all-air oxidation of cyclohexane is economically very attractive and has been heavily researched. Early work was performed by Gulf Research and Development [56–58], Asahi Chemical Industries [59], [60], and others [61]. For example, cyclohexane is oxidized in one step to adipic acid in 70 – 75 % yield, in the presence of a cobalt acetate catalyst in acetic acid as solvent [59]. More recently, there has been renewed interest in this work, and several patents have been issued to Redox Corporation and Bayer. [62–65].

Adipic acid can be produced by ozonolysis of cyclohexene [66] or by addition of a carboxylic acid to cyclohexene and subsequent oxidation of the resulting ester with nitric acid [67]. Formation of adipic acid derivatives by electrolytic coupling of acrylates has also been described [68].

5. Byproducts

The major byproducts of nitric acid oxidation of KA are glutaric acid [*110-94-1*] and succinic acid [*110-15-6*], and minor amounts of pentanoic acid and hexanoic acid are also formed. In commercial operations, the nitric acid reaction medium (NML) contains high concentrations of glutaric and succinic acids, resulting from the recycling of the mother liquor after crystallization of the adipic acid. A portion of this stream is diverted and processed separately to remove the byproduct acids and recover nitric acid and the copper and vanadium catalysts. Early commercial processes discarded these byproduct acids. However, most companies now recover these acids either as a mixture of dibasic acids (DBA) or convert them to dibasic esters (DBE) for a variety of uses.

Following the removal of the copper and vanadium by ion exchange and distillation of the nitric acid in water, methanol can be added to convert the acids to their methyl esters. Then the esters are distilled to give a mixture or the individual esters [69–71].

Sometimes the acids are removed by distillation to produce a mixture of acids and anhydrides, especially glutaric anhydride [*108-55-4*] and succinic acid [*108-30-5*] [72–76]. Separation of the individual acids by crystallization and extraction with organic solvents has been described [77], [78]. Other means of separating the byproduct acids include addition of inorganic salts [79], a $C_1 - C_6$ primary alkylamine [80], or urea [81], and extraction by a ketone solvent [82].

6. Quality Specifications

Commercial adipic acid is one of the purest large-scale manufactured chemicals because of the stringent requirements of its major consumer, the synthetic fibers industry. The U.S.

FDA has approved adipic acid as a food additive. Because essentially all adipic acid manufacturers use a nitric acid oxidation process, impurities are similar. Purity is affected mostly by variations in the synthesis of the KA intermediate and in the extent of adipic acid recrystallization and purification. Some typical specifications for food-grade adipic acid are: color, APHA equivalence (Hazen) 10 max., water 0.2 % max., ash on ignition 10 ppm max., iron 1.0 ppm max., adipic acid content 99.6 % min. [83].

Procedures for analysis of food-grade adipic acid are described in [84]. General methods for water (Karl Fischer), color in methanol solutions (APHA), iron, and other metallic impurities in commercial acid have been summarized [85]. Resin-grade adipic acid frequently has limits for succinic (ca. 50 ppm) and caproic (ca. 30 ppm) acids, and for hydrocarbon oils (ca. 15 ppm). Carboxylic acids can be determined by gas chromatography of their esters or by liquid chromatography of the free acids [86]. Total nitrogen can be determined by chemical reduction and distillation of ammonia from an alkaline solution. Hydrocarbon oil may be determined by IR analysis of a halocarbon extract of a solution of the salt.

7. Storage and Transportation

Adipic acid is conveyed pneumatically or mechanically from the drying equipment to the storage or shipping container. These containers may be aluminum or stainless steel railroad hopper cars, trucks, plastic bags, or drums. Principal hazards in handling adipic acid are the danger of dust explosion and skin or mucus membrane irritation on exposure to the dust. Particle size control and flow characteristics are also important factors due to the tendency of adipic acid that contains excessive fines to cake during storage.

8. Derivatives

8.1. Adiponitrile

The most important derivative of adipic acid is adiponitrile, 1,6-hexanedinitrile, 1,4-dicyanobutane, [*111-69-3*], M_r 108.14, *bp* 298 – 300 °C (at 101.3 kPa), 154 °C (at 1.3 kPa), *fp* 2.4 °C, n_D^{25} 1.4370, d_4^{25} 0.9599, an intermediate in the manufacture of the other major nylon 66 component, 1,6-hexanediamine. The original production process involved conversion of the acid to the dinitrile by liquid- [87] or vapor-phase dehydration [88] of the ammonium salt in the presence of phosphoric acid or a boron – phosphorus catalyst. Although this was the predominate technology used for adiponitrile production in the past, it is no longer used by any major nylon 66 producers.

Other routes which have been used include a process by Celanese, which in the 1960s and 1970s avoided manufacturing adiponitrile by producing 1,6-hexanediamine from ammonolysis of 1,6-hexanediol, which in turn was made by the hydrogenation of adipic acid [89]. This adipic acid based route was shut down around 1980. In 1948, DuPont introduced, and for several years operated, a process based on furfural [90]. From 1951 to 1983, DuPont operated a butadiene chlorination process [91]. The intermediate 1,4-dichloro-2-butene was converted to 3-hexenedinitrile with sodium cyanide and then hydrogenated to adiponitrile. Current adiponitrile manufacture is based on either propylene or direct hydrocyanation of butadiene.

In 1965 Monsanto introduced a process involving the electrolytic coupling of acrylonitrile [92]. This process, or variations of it, is also used in the United Kingdom and Japan. DuPont began the direct hydrocyanation of butadiene in 1972 [93]. Now all DuPont adiponitrile production, including a joint venture with Rhône-Poulenc (now Rhodia) in France, uses this technology. The process consists of a two step hydrocyanation, catalyzed by a nickel(0) phosphite complex and promoted by certain Lewis acids [94–96]. The mixture of isomeric pentenenitriles and methylbutenenitriles produced in the first step is isomerized to predominately 3- and 4-pentenenitrile [97–99]. Subsequent anti-Markovnikov addition of hydrogen cyanide to the pentenenitriles produces adiponitrile.

Other routes that have been revealed include chemical dimerization of acrylonitrile to 3-hexenedinitrile [100–102] and hydrocyanation of butadiene with a copper halide catalyst to yield 3-pentenenitrile [103], followed by disproportionation to dicyanobutenes and

butenes. Finally, another dimerization route to adiponitrile involves the addition of acrylonitrile to 2-methyleneglutaronitrile in the presence of zinc or cobalt complexes and a Lewis base [104]. The dimer is then hydrocyanated to 1,2,4-butanetricarbonitrile followed by dehydrocyanation to 3-hexenedinitrile [105].

8.2. Other Derivatives

Salts. Adipic acid forms alkali metal and ammonium salts that are water-soluble and alkaline earth salts that are only moderately soluble. Their solubilities in 100 g of water are: diammonium salt [*3385-41-9*] 40 g (14 °C), disodium salt [*7486-38-6*] 59 g of hemihydrate (14 °C), dipotassium salt [*19147-16-1*] 65 g (15 °C), calcium salt [*22322-28-7*] 4 g of monohydrate [*18850-78-7*] (13 °C), 1 g of anhydrous salt (100 °C).

The most common salt is poly(1,6-hexanediammonium hexanedioate), produced by interaction of adipic acid with 1,6-hexanediamine. This water-soluble salt, the precursor to nylon 66, is readily shipped or stored prior to the final polyamidation, which occurs with the removal of water. The chemistry of this step has been reviewed [106].

Esters and Polyesters. The esters and polyesters of adipic acid constitute the largest non-polyamide market for adipic acid. Esters made from long-chain alcohols are used as plasticizers and lubricants, while those from short-chain alcohols are used primarily as solvents. Refluxing adipic acid with methanol in the presence of an acid catalyst can produce monomethyl adipate, along with the diester. Electrolysis of the salt of the monoester (Kolbe synthesis) produces dimethyl sebacate, another polyamide precursor. The boiling points of some esters are listed in Table 1. The esters dissolve readily in most organic solvents. While dimethyl adipate is the most commonly used solvent, di-2-ethylhexyl adipate is the most widely used plasticizer. Other simple adipate plasticizers include the *n*-octyl, *n*-decyl, isodecyl, and isooctyl esters. More complex polymeric plasticizers, prepared from glycols, account for a little less than half the adipic acid based plasticizers. Low molecular mass polyester polyols having hydroxyl end groups are used with polyisocyanates to produce polyurethane resins.

Table 1. Boiling points of adipic acid esters

Ester		*p*, kPa	*bp*, °C
Monomethyl	[*627-91-8*]	1.3	158
Dimethyl	[*627-93-0*]	1.7	115
Monoethyl	[*626-86-8*]	0.9	160
Diethyl	[*141-28-6*]	1.7	127
Di-*n*-propyl	[*106-19-4*]	1.5	151
Di-*n*-butyl	[*105-99-7*]	1.3	165
Di-2-ethylhexyl	[*103-23-1*]	0.67	214
Di-*n*-nonyl	[*151-32-6*]	0.67	230
Di-*n*-decyl	[*105-97-5*]	0.67	244

Anhydrides. The usual form of the anhydride produced by dehydrating adipic acid is the linear, polymeric form [*2035-75-8*]. Distillation of the polymeric anhydride is said to produce the monomeric cyclic form, which is very unstable and reverts readily to the linear, polymeric anhydride.

Amide. The diamide, $C_6H_{12}N_2O_2$ [*628-94-4*], *mp* 228 °C, is practically insoluble in cold water. It has been traditionally prepared from the dimethyl ester by treatment with concentrated ammonium hydroxide or by heating the diammonium salt of adipic acid in a stream of ammonia. Other substituted amides can be prepared from amines by the usual synthetic methods.

9. Uses

About 80 % of worldwide adipic acid consumption is used for the manufacture of nylon 66 fibers and resins. This is down from about 87 % in 1981. Table 2 summarizes consumption in three major regions of the world. A small amount of adipic acid is still used captively to produce adiponitrile.

Large amounts are converted to esters for use in plasticizers, lubricants and in a variety of polyurethane resins. The monomeric esters are important plasticizers for poly(vinyl chloride) and other resins, while polymeric esters are used when unusually high plasticizer levels are required. Polyurethane resins employing adipic acid are produced from polyisocyanates and polyester polyols (adipates). These are used

in specialty foams, lacquers, adhesives, surface coatings and spandex fibers for stretch-wear.

Table 2. Adipic acid consumption, 10^3 t/a [107–110]

	United States		Western Europe		Japan	
	1991	1995	1991	1995	1991	1995

Nylon 66 resin	115	193	86	110	23	26
Plasticizers	30	38	21	24	13	14
Polyurethane resins	38	39	28	45	18	13
Miscellaneous	17	23	66	88	19	17

Adipic acid is added to gelatins and jams as an acidulant and to other foods as a buffering or neutralizing agent. It is also used to modify the properties of unsaturated polyesters for use in reinforced plastics and alkyd coatings. Polyamide – epichlorohydrin resins employing adipic acid are used to increase the wet strength of paper products. Other miscellaneous applications are in the adhesives, insecticide, tanning and dying, and textile industries. Adipic acid and mixed dibasic acids (DBAs) are being used as buffers in flue gas desulfurization treatment in power plants [111].

10. Economic Aspects

Capacities. Total worldwide annual capacity for adipic acid was 2.5×10^6 t/a in 1999 (Table 3). Although this reflects only a 15 % growth in capacity since 1980, it also reflects the shutting down of several adiponitrile plants which had used adipic acid as a starting material, thus making it available for other uses. The North American capacity was 1.06×10^6 t/a, or 42 % of the total, whereas Western Europe accounted for 35 %, produced mainly by the United Kingdom, France, Germany and Italy. Imports and exports have become significant. In 1995 U.S. exports were 71×10^3 t [112] or 8.5 % of U.S. consumption. This is up from 1.2 % in 1979 [113]. Since 1970, U.S. consumption of adipic acid has increased by 80 %, or about 3 % per year. Growth rates are expected to remain at about 3 % per year through 2000. Regional capacities are shown in Table 3, along with annual capacities for the major producing companies.

Table 3. Worldwide adipic acid capacity as of January 1999 [113]

Region	Capacity, 10^3 t/a	Major producers (capacity, 10^3 t/a)
North America	1058	DuPont (740), Solutia (295), Allied (23)
Western Europe	841	Rhodia (280), BASF (260), DuPont (220), Bayer (55), Radici (60), UCB
Far East	70	Asahi (120), DuPont (115), China (139), Korea (70)
Others	115	

Production. Adipic acid production is dominated by nylon 66 fiber and resin manufacture; as a result, the economic picture for the acid is strongly dominated by the markets for these materials. Less than 15 % of U.S. production is sold on the merchant market, essentially for non-nylon uses. This ratio is higher in Western Europe and Japan. The synthesis of adiponitrile from adipic acid, once significant, is no longer used by any major manufacturers. However, it continues to a very limited degree in some Eastern European countries. The non-nylon uses for adipic acid have grown at about 6 % per year since 1970. Production costs closely parallel raw material prices (cyclohexane and ammonia), which in the late 1990s have fallen with the decline in crude oil prices. The largest growth rate for adipic acid, as well as nylon 66, is in China and the Far East. The projected growth rate in the United States and Western Europe is expected to be slow, so the supply/demand picture should remain relatively constant for the next few years.

11. Toxicology and Occupational Health

Adipic acid is a minor irritant of low oral toxicity. The lowest published lethal dose (LDLo) is 3600 mg/kg (rat, oral), LD_{50} 275 mg/kg (rat or mouse, i.p.), LD_{50} 1900 mg/kg (mouse, oral) [114]. Some delayed body weight increases and changes in certain enzymes and in urea and chloride level in the blood were observed in chronic feeding tests [115]. No teratogenic activity was detected in studies with pregnant mice [116]. In metabolism studies with rats fed ^{14}C-labeled

adipic acid, both unchanged adipic acid and normal metabolic products were detected in the urine [117], [118].

Exposure of the mucous membranes (eyes, respiratory tract) produces irritation; prolonged exposure to the skin can be drying or irritating. In case of spills or leaks, personnel should be protected from inhalation or excessive skin contact. Dusting should be controlled and static sparks should be avoided. Water may be used to flush the area.

Although no TLV or MAK has been established, the airborne exposure should be less than that of an organic nuisance dust: ACGIH (1979) 8-h TWA 10 mg/m^3 (total dust) and 8-h TWA 5 mg/ m^3 (respirable dust) (OSHA TLV is 15 mg/ m^3 for total dust). Toxicity data from representative types of adipic acid derivatives are shown in Table 4.

Table 4. Toxicity data for adipic acid derivatives [119]

Derivative	Oral LD_{50} (rat) mg/kg	Inhalation LC_{50} (rat, 4 h), mg/m^3	Other LD_{50}, mg/kg
Adiponitrile	300	1710	50 (guinea pig, s.c.)
Di-2-ethylhexyl adipate	9110	–	900 (rat, i.v.)
Dimethyl adipate	–	–	1809 (rat, i.p.)
Adipamide	500		
Magnesium adipate	–	–	180 (mouse, i.v.)

1. Introduction

Industrially, the most important alcohols are methanol, ethanol, 1-propanol, 1-butanol, 2-methyl-1-propanol (isobutyl alcohol), the plasticizer alcohols (C_6 – C_{11}), and the fatty alcohols (C_{12} – C_{18}), used for detergents. They are prepared mainly from synthesis gas alone (methanol), from olefins via the oxo synthesis, or by the Ziegler process.

Apart from the applications mentioned above, alcohols are used as solvents and diluents for paints (mainly C_1 – C_6 alcohols) [4], as intermediates in the manufacture of esters and a whole range of organic compounds, as flotation agents, as lubricants, and as fuel or fuel additives, e.g., methanol, ethanol, *tert*-butyl alcohol.

For industrial purposes, isomeric mixtures often are preferred because the pure alcohols are too expensive. Moreover, mixtures of alcohols with differing numbers of carbon atoms can be advantageous for certain purposes. Therefore, the amounts of alcohol mixtures available on the market are similar to the quantities of the pure, individual alcohols.

2. Saturated Alcohols

2.1. Physical Properties

Some physical properties of saturated $C_1 - C_{26}$ alcohols are given in Table 1. Up to C_{10}, the straight-chain alcohols are colorless liquids at room temperature with characteristic odors. The higher alcohols are solid, waxy substances. Because of hydrogen bonding, the boiling points are considerably higher for alcohols, especially lower-molecular-mass ones, than for the corresponding hydrocarbons. With increasing molecular mass, however, the influence of the hydroxyl group becomes less. For example, the degree of association at room temperature is 3.17 for methanol but only 1.12 for decanol.

Methanol, ethanol, and the propanols are completely miscible with water. With increasing molecular mass, the solubility decreases significantly. For example, the solubility of 1-butanol in water is 7.7 %, and that of decanol less than 0.01 % [5]. The data for some azeotropic mixtures with water are compiled in Table 2.

Table 2. Azeotropic mixtures with water [9]

Alcohol	*bp* of alcohol, °C	*bp* of azeotrope, °C	Water in azeotrope, wt %
Ethanol	78.32	78.174	4.0
1-Propanol	97.2	87.7	28.3
2-Propanol	82.4	80.3	12.6
1-Butanol	117.7	92.3	37.0
Isobutyl alcohol	107.9	89.9	33.2
sec-Butyl alcohol	99.4	87.5	27.3
tert-Butyl alcohol	82.5	79.9	11.76
1-Pentanol	138.0	95.8	54.4
2-Pentanol	119.3	91.7	36.5
3-Pentanol	115.4	91.7	36.0
2-Methyl-1-butanol	128.0	93.8	41.5
3-Methyl-1-butanol	132.0	95.15	49.6
2-Methyl-2-butanol	101.8	87.35	27.5
3-Methyl-2-butanol	112.5	91.0	33
1-Hexanol	157.1	97.8	75
1-Heptanol	176.2	98.7	83
1-Octanol	195.15	99.4	90
2-Ethylhexanol	184.7	99.1	80.0

The temperature dependence of vapor pressure, heat of vaporization, specific heat, density, viscosity, surface tension, and thermal conductivity is given in [6] for methanol, ethanol, propanol, and butanol. For nomograms to determine the thermodynamic data of straight-chain alcohols, see [7]. The physical data of alcohols employed as solvents are summarized in [8], [9].

2.2. Chemical Properties

Reactions of alcohols can be characterized by cleavage of the O–H bond or the C–O bond either homolytically or ionically. The chemical properties of greatest industrial importance are as follows.

Oxidation and Dehydrogenation. Under normal conditions alcohols are stable. Oxidation with chemical agents, such as chromic acid or permanganate, leads to a variety of products depending on the nature of the alcohol. Primary alcohols are oxidized first to aldehydes and then to carboxylic acids; secondary alcohols are oxidized to ketones. Catalytic oxidation or dehydrogenation of primary and secondary alcohols on copper, silver, iron, molybdenum, etc., catalysts lead to the formation of aldehydes and ketones. In the Oppenauer oxidation a secondary alcohol is dehydrogenated by an excess of a ketone, e.g., acetone, in the presence of aluminum isopropoxide:

$$R^1-CHOH-R^2 + CH_3-CO-CH_3 \underset{}{\overset{Al(OC_3H_7)_3}{\rightleftharpoons}} R^1-CO-R^2 + CH_3-CHOH-CH_3$$

Reduction. With hydrogen iodide or zinc and hydrochloric acid, alcohols are converted to hydrocarbons. Catalytic hydrogenolysis is especially successful with benzyl alcohols.

Dehydration. Water can be split from alcohols by heating them in the presence of strong acid or by passing them over aluminum oxide, silicic acid, or synthetic zeolites. As a rule, not only those products that result from a β-elimination are formed, but also compounds with an isomerized double bond. The isomerization can be suppressed by the addition of amines. Tertiary alcohols can be dehydrated more easily than secondary or primary alcohols.

Under less severe conditions symmetric ethers are formed from alcohols in an intermolecular reaction:

$$2\ ROH \longrightarrow ROR + H_2O$$

The same compounds that accelerate the intramolecular dehydration are suitable as catalysts.

Alcohols as Alkylation Reagents. Alcohols react with ammonia and amines to form *N*-alkyl or *N*,*N*-dialkylamines. Aromatic hydrocarbons are alkylated by alcohols in the presence of Friedel-Crafts catalysts.

Esterification. In the presence of acid catalysts, alcohols react with organic or inorganic acids, acid chlorides, or anhydrides to form esters (→ Esters, Organic).

Addition Reactions. Alcohols add to aldehydes and ketones to form acetals (→ Aldehydes, Aliphatic and Araliphatic). Alkylpolyglycol ethers are obtained with alkylene oxides. The addition to acetylene gives vinyl ether; addition to olefins yields mixed ethers.

For further reactions of alcohols see [10].

2.3. Production

The following processes have been realized on an industrial scale:

1) Synthesis from carbon monoxide and hydrogen (C_1)
2) Oxo synthesis (mostly combined with hydrogenation of the initially formed aldehydes; C_3-C_{20})
3) Hydrogenation of aldehydes, carboxylic acids, or esters
4) Aldol condensation of lower aldehydes and hydrogenation of the alkenals ($C_3 \rightarrow C_6$, $C_4 \rightarrow C_8$, $C_8 \rightarrow C_{16}$)
5) Oxidation of trialkylaluminum compounds (Ziegler process)
6) Oxidation of saturated hydrocarbons
7) Hydration of olefins (C_2-C_4)
8) Homologation of alcohols
9) Hydrocarbonylation by the Reppe process
10) Hydrocarboxymethylation
11) Fermentation processes (C_2-C_5)
12) Guerbet process

The most important industrial processes are the methanol synthesis, with an annual production of ca. 12×10^6 t, and the oxo synthesis, with ca. 4.5×10^6 t. However, the hydration of ethylene and propene to ethanol and 2-propanol, and the oxidation of trialkylaluminum compounds (Alfol process or Ziegler process) also have achieved considerable commercial significance. Fermentation, especially for the production of ethanol, has become important again in certain regions because of the increased price of oil.

2.3.1. Synthesis from Carbon Monoxide and Hydrogen

On a commercial scale only methanol is prepared from synthesis gas (→ Methanol). Synol, isobutylol, oxyl, and similar processes led to a mixture of oxygen-containing compounds with alcohols as the main components [11], [12]. These methods are no longer used in the Western World. Newer developments also produce oxygen-containing compounds [13] or alcohol mixtures [14].

In the IFP (Inst. Français du Pétrole) process for higher alcohols [14], highly activated catalysts are used under low-pressure methanol synthesis conditions. The catalyst contains mixed oxides of copper and cobalt plus at least one other metal (Al, Ce, Cr, Fe, La, Mn, Pr, Nd, Y, or Zn) and at least one Group I or II metal compound. The higher alcohol content can be varied from 20–50 wt % by changing the catalyst composition. A number of byproducts, such as hydrocarbons, esters, and ketones, also are produced.

However, none of these newer processes are used in industry.

Small amounts of higher alcohols are formed as byproducts of the Fischer-Tropsch synthesis [15] (→ Coal Liquefaction).

2.3.2. Oxo Synthesis

For details → Oxo Synthesis.

Alcohols in the range C_3-C_{20} can be prepared by the oxo synthesis, in which olefins react with synthesis gas to form aldehydes, which in turn are hydrogenated.

One particular version of the oxo synthesis is the *Shell process*; the strong hydrogenating activity of the catalyst, $HCo(CO)_3PR_3$, leads to the direct hydrogenation in the oxo reactor of the initially formed aldehyde [16]:

$$R-CH=CH_2 + CO + 2\,H_2 \xrightarrow{\text{cat.}} R-CH_2CH_2CH_2OH$$

The process was first applied commercially on a propene basis in 1963 and used for the manufacture of 1-butanol and 2-ethylhexanol [17]. In 1965 it was developed further to produce detergent alcohols. It is used primarily to make higher alcohols.

Planned or actual expansions of the Shell process capacity in the United States (previously 250000 t/a) by 46000 t/a, of surfactant alcohols in the Federal Republic of Germany by 56000 t/a, and of Mitsubishi's in Japan by 70000 t/a [18], will increase world capacity to some 470000 t/a.

The Shell process has the advantage that olefins with an internal double bond can be hydroformylated, because under the reaction conditions, isomerization of the double bond takes place, and α-olefins are formed. For example, ω-olefin fractions obtained from ethylene by the "SHOP process" of Shell [19] (→ Hydrocarbons, Chap. 2.) can be converted with synthesis gas to alcohols. The alcohol mixtures formed consist of up to 80 % linear compounds and are used in the plasticizer and detergent fields.

2.3.3. Hydrogenation of Aldehydes, Carboxylic Acids, and Esters

Aldehydes can be hydrogenated in the presence of homogeneous or heterogeneous catalysts [20], [21]. Homogeneous systems are advantageous only if sulfur-containing starting materials, which would poison the heterogeneous catalysts, are used or if the hydrogen for the hydrogenation contains carbon monoxide.

Generally, however, heterogeneous catalysts are preferred. These are effective both in the gas phase at temperatures of 90 – 180 °C and pressures of 25 bar and in the liquid phase at 80 – 220 °C and pressures up to 300 bar. The hydrogenation temperature applied in industrial processes represents a compromise between the best possible energy utilization and high catalyst lifetimes.

For continuous processes, catalysts in fixed-bed systems are favored. The aldehyde, either as vapor strongly diluted with excess hydrogen [22] or as liquid together with hydrogen [23], is fed through the high-pressure pipe containing the catalyst bed. To remove the heat generated by the reaction, the hydrogen is circulated through a heat exchanger. The especially important hydrogenation of 2-ethyl-2-hexenal usually is carried out in a single step on a nickel-containing catalyst [24]. Similar one-step processes have been suggested [25]. However, two-step processes are also common, whereby the main hydrogenation takes place in the gas phase (e.g., on copper-containing catalysts), and the second in a liquid phase or trickle-bed process (e.g., on nickel-containing catalysts).

The catalysts usually are supported on aluminum oxide or silica gel. In addition to nickel and copper, also zinc, chromium, and combinations of these metals have been used successfully as catalysts [26].

For the manufacture of fatty alcohols, the corresponding carboxylic acid esters are hydrogenated (for details → Fatty Alcohols). Starting materials are natural fats and oils, which are first transesterified to the methyl esters and then reduced to the alcohols, either with sodium (Bouveault-Blanc reduction) or by catalytic hydrogenation. The reduction with sodium enables the preparation of unsaturated fatty alcohols from the esters of unsaturated fatty acids.

The hydrogenation of fatty acids and fatty acid esters requires more drastic conditions than the aldehyde hydrogenation. The process operates continuously or discontinuously and makes use of copper–chromium oxide catalysts (Adkins catalysts), which are either suspended or placed in a fixed bed. Reaction temperatures of 240 – 300 °C and pressures of 200 – 300 bar are normal. By modifying the catalysts (e.g., by addition of cadmium) unsaturated fatty acid esters can be converted directly to unsaturated fatty alcohols [27].

2.3.4. Aldol Condensation of Lower Aldehydes and Hydrogenation of the Alkenals

In industry, the only source of aldehydes for the aldol condensation is the oxo synthesis [21]. After the isoaldehydes and byproducts are removed, the condensation is catalyzed by acids or bases (→ Aldehydes, Aliphatic and Araliphatic, Chap. 4.2.). Because the reactivity of each aldehyde depends on the chain length and the degree of branching, the reaction conditions are

adapted according to the individual compound. The alkenals, formed from the aldols by elimination of water, are hydrogenated over heterogeneous catalysts. As a rule the same catalysts are used as for the hydrogenation of oxo aldehydes. 2-Ethylhexanol, 2-methylpentanol, and limited amounts of highly branched, isomeric C_{16} and C_{18} alcohols are prepared by this method. The so-called aldox process, in which the aldehyde mixture formed in the oxo synthesis is subjected to aldol condensation in the oxo reactor, has not become established because of the presence of mixed aldols in the final products; however, some mixed aldols of acetaldehyde with higher aldehydes are important.

2.3.5. Oxidation of Trialkylaluminum Compounds

Ethylene can add to triethylaluminum to form a mixture of trialkylaluminum compounds of higher molecular mass [28]. These products can be oxidized with air to the corresponding aluminum alkoxides, which are then hydrolyzed to a mixture of linear primary alcohols with the same number of carbon atoms as the alkyl groups of the trialkylaluminum components [1–3]:

$$-\overset{|}{Al}-C_2H_5 + x\,C_2H_4 \longrightarrow -\overset{|}{Al}-(CH_2CH_2)_x-C_2H_5$$
$$\xrightarrow{O_2} -\overset{|}{Al}-O-(CH_2CH_2)_x-C_2H_5$$
$$\xrightarrow{H_2O} HO-(CH_2CH_2)_x-C_2H_5 + -\overset{|}{Al}-OH$$

On the basis of this reaction, called the Ziegler process, two commercial processes have been developed, one by Conoco, in operation in the United States since 1962 and in the Federal Republic of Germany by Condea Chemie (Conoco and Deutsche Texaco) since 1964; and the other by the Ethyl Corp., in operation since 1965. The principal differences between the two processes are the chain-length distribution and the linearity of the alcohols produced, as well as the technical process characteristics for the generation and control of this distribution.

Alfol Alcohol Process (Conoco Process). The chain-growth reaction is carried out at a temperature as low as possible in order to prevent displacement reactions that lead to the formation of olefins. The chain-length distribution corresponds to a Poisson curve. The resulting alcohols are practically 100 % linear. A broad range of alcohols (C_2-C_{28}) is typical for the Alfol alcohol process. Although the process can be varied to either increase or decrease the chain lengths of the manufactured alcohols, the distribution pattern remains the same.

Process with Controlled Linear Chain Growth. The Ethyl Corp. has successfully developed a process which forms predominantly C_{12} and C_{14} alcohols. The alcohols are up to 95 % linear.

The product distributions obtained in the Conoco and the Ethyl Corp. processes are compared in Table 3.

Table 3. Composition of the alcohol mixtures from the Ziegler process

C no.	Conoco	Ethyl Corp.
6	9.6	1.4
8	16.9	3.2
10	20.7	7.7
12	19.4	34.5
14	15.1	26.3
16	9.8	16.7
18	5.3	8.9
20	3.2	1.3

2.3.6. Oxidation of Saturated Hydrocarbons

Bashkirov Oxidation. The oxidation of aliphatic hydrocarbons with air in the presence of boric acid gives boric acid esters in high yield. These are hydrolyzed in a second step to secondary alcohols in which the hydroxyl groups are distributed statistically along the molecular chain [29–31].

The reaction passes through an intermediate secondary hydroperoxide, for the reaction mechanism see [31], [32]. Normally a mixture of *n*-hydrocarbons with chain lengths between 10 and 16 is used as feedstock. The oxidation is carried out in the liquid phase at 150 – 170 °C in the presence of 4 – 5 wt % metaboric acid. A nitrogen-oxygen mixture (ca. 3.5 % O_2) is used at normal or slightly elevated pressure. In newer plants amines are added as co-catalysts [31]. The resulting metaboric acid esters or boroxines are resistant to oxidation and thermally stable. To obtain economically acceptable selectivities of 80 – 85 % , the level of conversion must be held below 20 %.

Starting material and oxidation byproducts are removed by flash evaporation and are cleaned in alkaline and water scrubbers; the *n*-hydrocarbons are recycled [30]. The metaboric acid esters at the bottom of the flash column are hydrolyzed by the addition of small amounts of water at 80 – 100 °C. Impurities (mostly carbonyl compounds) are removed by alkaline and water washes. After fractional distillation, alcohols are obtained with a purity greater than 98 %. Processing concludes with "hydrofinishing" (hydrogenation over heterogeneous nickel catalysts) to remove colored and odorous substances.

The orthoboric acid in the aqueous solution is converted to metaboric acid by dehydration. Recovery also is possible by crystallization. In more recent process variants the boric acid concentrate is mixed with the *n*-hydrocarbons and the mixture dehydrated, preventing agglomerations and stoppages. The dried slurry is returned to the oxidation reactor.

In the 1950s Bashkirov developed the original German work into a commercial process [28], [33]. The first plant began production in Shebekino/Belgorod, USSR, in 1959 [34]. Plants were operated in the Soviet Union [34] and in Japan [31]. The Union Carbide (UCC) plant in the United States was closed in 1977 [31].

The secondary alcohols produced in this process usually are converted to alkylphenol ethoxides and used as detergents. The costly recirculation of hydrocarbons and boric acid as well as disadvantages in the application of secondary alcohols [35], however, have prevented this process from achieving any great significance in the Western World.

A further important use of boric acid-catalyzed oxidation is the preparation of cyclohexanol and cyclohexanone from cyclohexane [36] (intermediate products in the manufacture of caprolactam, adipic acid, and phenol), and of cyclododecanol (intermediate product in the nylon 12 synthesis) and cyclododecanone from cyclododecane [37]; → Cyclohexanol and Cyclohexanone; → Cyclododecanol, Cyclododecanone, and Laurolactam.

Oxidation with Alkyl Hydroperoxides. Alcohols also can be obtained by hydroxylation of alkanes with alkyl hydroperoxides [38]. Iron porphyrins are especially useful as catalysts.

$$RH + R'OOH \xrightarrow{cat.} ROH + R'OH$$

Alcohols from Fatty Acids Produced by Hydrocarbon Oxidation. The oxidation of hydrocarbons with air in the presence of manganese catalysts leads to a complex mixture of reaction products [39]. The initially formed alcohols are oxidized further to ketones and acids, → Fatty Acids. At present the process is operated mainly in the former Soviet Union. The production of fatty acids in this way has roughly the same order of magnitude as that of fatty acids from native raw materials in the United States [3].

Processing of the reaction mixture is difficult, because not all byproducts can be removed. Therefore, these fatty acids do not reach the same standards of quality as natural fatty acids.

Alcohols are formed from fatty acids by esterification of the fractionated raw acids (mostly in the $C_{10} - C_{15}$ range) with methanol or butanol and subsequent hydrogenation. With linear hydrocarbons as starting materials, linear alcohols can be produced; however, depending on the catalyst, the specific hydrocarbon, and the reaction conditions, the alcohol mixture contains 5 – 15 % branched-chain alcohols. Owing to the impurities present in the fatty acids, the alcohols prepared from them contain odorous substances, so their range of applications is limited.

According to estimates [3], about 10 % of these synthetic fatty acids are processed to alcohols. The annual production in Eastern Block countries is presumed to be at least 50000 t/a.

2.3.7. Hydration of Olefins

A common method for the production of lower alcohols is the hydration of alkenes. In accordance with Markovnikov's rule, secondary and tertiary alcohols are formed (except in the case of ethylene).

$$R-CH=CH_2 + H_2O \xrightarrow{H^+} R-CHOH-CH_3$$

The rate of this reaction is determined by the stability of the intermediate carbenium ion (tertiary > secondary > primary). Therefore the hy-

dration of isobutene proceeds at room temperature in the presence of low H^+ ion concentrations owing to the relative stability of the intermediate tertiary carbenium ion. The hydration of ethylene, in contrast, requires elevated temperatures and pressures [10].

Industrially two variants of the hydration reaction are used. In the so-called *indirect process,* the liquid-phase reaction takes place in two steps. In the first, the olefin reacts with sulfuric acid to form mono- and dialkylsulfates, which, after dilution with water, are hydrolyzed to the alcohol. However, in order to recycle the sulfuric acid, a costly reconcentration is necessary.

In the *direct process,* hydration occurs in the gas phase. Because the reaction is exothermic and is accompanied by a reduction in volume (2 mol of reactant form 1 mol of product), the alcohol formation is favored by high pressure and low temperature. Because the conversion is incomplete, a costly gas recycle is necessary. Phosphoric acid-containing materials, e.g., celite, are efficient catalysts. However, increased use is made of ion exchangers.

The primary use of direct hydration is for the preparation of ethanol from ethylene (→ Ethanol) and of isopropyl alcohol from propene (→ Propanols). It is also important in the production of 2-butanol from a mixture of 1-butene and 2-butene (raffinate II) and of *tert*-butyl alcohol from isobutene.

2.3.8. Homologation of Alcohols

Homologation is the reaction of alcohols with synthesis gas in the presence of complex, multicomponent catalyst systems. Depending on reaction conditions the products are aldehydes or alcohols containing one CH_2 group more than the starting materials [40–43]:

$$RCH_2OH + CO + H_2 \xrightarrow{cat.} RCH_2CHO + H_2O$$
$$RCH_2OH + CO + 2\,H_2 \xrightarrow{cat.} RCH_2CH_2OH + H_2O$$

Although the reaction was originally conceived for the synthesis of ethanol from methanol [44], [45], the scope has been extended to include the production of homologous aldehydes (acetaldehyde from methanol), carboxylic acids (propionic acid from acetic acid), carboxylic acid esters (ethyl acetate from methyl acetate), as well as the synthesis of styrene (via the homologation of benzyl alcohol to 2-phenylethanol with subsequent dehydration) [28], [31].

So far, homologation has not been used industrially because conversion and selectivity, despite considerable advances [28], are still insufficient and because there are problems with recycling the complex homologation catalysts.

2.3.9. Reppe Process

The Reppe hydrocarbonylation of olefins with carbon monoxide and water and using ammonium salts of tetracarbonyldihydrido iron as catalyst leads to alcohols [46] (→ Carbonylation):

$$C_3H_6 + 3\,CO + 2\,H_2O \xrightarrow{cat.} C_4H_9OH + 2\,CO_2$$

As in the oxo synthesis, branched-chain products also are formed (molar ratio of linear to branched-chain alcohols is ca. 9 : 1).

Propene reacts at 90 – 110 °C and 5 – 20 bar to form butanols with yields of 90 %. Approximately 4 % of the propene is hydrogenated to propane. The conversion of higher olefins requires more extreme conditions.

The process cannot compete with hydroformylation. The only plant using it to manufacture butanol from propene (Japan Butanol Co., capacity 30000 t/a) closed several years ago [47].

2.3.10. Hydrocarboxymethylation

Hydrocarboxymethylation is a variant of the Reppe process in which higher olefins react with carbon monoxide and methanol in the presence of a cobalt-pyridine catalyst. The products are esters of carboxylic acids containing one more carbon atom in the parent chain than the olefin feedstock [48]. The esters can be hydrogenated to the alcohols. For economic reasons – at the present time the products can be prepared more cheaply from natural raw materials – the process has not as yet achieved any significance.

2.3.11. Fermentation

Fermentation, probably the oldest process for the manufacture of ethanol (→ Ethanol), is still

practiced on a large scale [49]. The butanol-acetone fermentation of carbohydrate raw materials is no longer of any importance [50]. On a small scale, pentanols are recovered from fusel oils [10], [51].

2.3.12. Guerbet Alcohols

In the Guerbet process saturated primary alcohols are dimerized to α-branched primary alcohols [52]. Normally the reaction is carried out by refluxing the alcohol in the presence of an alkaline condensation agent and a hydrogenation-dehydrogenation catalyst, e.g.:

$$2\,n\text{-}C_6H_{13}OH \xrightarrow[\text{Raney Ni}]{\text{NaOH}} C_6H_{13}\overset{\overset{C_4H_9}{|}}{C}H-CH_2OH + H_2O$$

The water and small amounts of hydrogen produced in the reaction are removed continuously. For the mechanism of the reaction see [53], [54]. If heating is carried out for long periods, trimeric α-branched primary alcohols also are formed.

The yield of dimeric alcohols is about 80 %. It can be increased by recycling the residues and portionwise addition of fresh catalyst [55]. Metallic sodium, as well as a number of other substances have been proposed as condensation agents [10]. For industrial purposes alkali metal hydroxides are preferred.

Alcohols having chains shorter than cetyl alcohol (C_{16}) preferably are dimerized at higher pressure [56]. Using this process, short-chain alcohols can be converted into $C_{10}-C_{20}$ alcohols. Examples include 2-hexyldecanol [57] and 2-octyldodecanol [58], which find application in cosmetics as oily components with favorable solvent properties.

Because alcohols with the typical α-branching [59] are prepared more easily by other methods, e.g., 2-ethyl-1-hexanol by hydroformylation of propene to give butanal and subsequent aldol condensation, the Guerbet reaction has not become established as a large-scale industrial process.

2.3.13. Other Processes

Of commercial interest is the epoxidation of linear α-olefins and subsequent hydrogenating cleavage to plasticizer (C_6-C_{10}) or detergent ($C_{10}-C_{16}$) alcohols [60]. For hydrogenating cleavage a number of catalysts can be applied [61]. The selectivity towards primary alcohols can be influenced by the choice of catalyst, the hydrogenation conditions, and the use of solvents [10], [62].

The hydrolysis of carboxylic acid esters [63] is also of some importance. For a comprehensive review of other processes see [10].

2.4. Individual Alcohols

The following sections describe individual alcohols and special alcohol mixtures, classified according to increasing number of carbon atoms. In each case the specific method of manufacture, the main producers, and trade names, as well as the necessary basic feedstocks are mentioned.

The C_1-C_5 alcohols are described under individual keywords.

2.4.1. C_6 Alcohols

For physical properties see Table 1.

1-Hexanol [*111-27-3*], $CH_3(CH_2)_4CH_2OH$, is prepared according to the Ziegler process (see Section 2.3.5) from ethylene (Alfol 6, Condea; Epal 6, Ethyl Corp.) or is made from natural products derived from coconut or palm oils (Lorol C 6, Henkel). It is used as a solvent, as a basic material for the perfume industry, and for the production of plasticizers (in this case usually as a mixture with higher *n*-alcohols). Nitrates of 1-hexanol are recommended as cetane number improvers. Commercial specifications are given in Table 4.

2-Methyl-1-pentanol [*105-30-6*] is prepared by aldol condensation of propionaldehyde and subsequent hydrogenation of the intermediate 2-methyl-2-pentenal, (see Section 2.3.4). It is used as a solvent.

$CH_3(CH_2)_2CH(CH_3)CH_2OH$

Commercial specifications are given in Table 4. Manufacturers are, e.g., Ruhrchemie and UCC [69], [70].

Table 4. Typical specifications of commercial plasticizer alcohols [9], [64–76]

	Alcohol, wt %	Color, Hazen no. [a]	Density [b], g/cm^3	Boiling range [c], °C	Hydroxyl value [d], mg KOH/g	Acidity [e], mg KOH/g	Moisture [f], wt %	Carbonyl number [g]

[f] Karl Fischer reagent
[g] Oximation

4-Methyl-2-pentanol [*108-11-2*] is a byproduct of the synthesis of methylisobutylketone [*108-10-1*] (→ Ketones).

$(CH_3)_2CHCH_2CH(OH)CH_3$

The alcohol is sold by UCC, for example, under the name Methylamylalcohol [69]. It is used as a solvent in the paint industry, as a brake fluid, as a flotation aid [71], and as a fungicide [72].

2-Ethyl-1-butanol [*97-95-0*] is prepared by aldol condensation (→ Aldehydes, Aliphatic and Araliphatic) of 1-butanal and acetaldehyde and subsequent hydrogenation.

$(C_2H_5)_2CHCH_2OH$

It is a neutral, colorless, pleasant-smelling liquid and is employed as a solvent and flow improver for paints and varnishes, as a component in the manufacture of penetrating oils and corrosion inhibitors, as a cleaning agent for printed circuits, as an extracting agent for metal ions, and as the alcohol component in the manufacture of plasticizer phthalates for special uses, of nitric acid esters as cetane number improvers, and of phosphoric acid esters as plasticizer auxiliaries.

Manufacturers are, e.g., Ruhrchemie and UCC. Commercial specifications are given in Table 4.

C_6 Alcohol Mixtures. These are prepared by the hydroformylation of 1-pentenes and subsequent hydrogenation. Esso/Enjay offers, for example, an isomeric mixture under the name Hexanol that consists of 44 % 1-hexanol, 53 % 2-methylpentanol, and 3 % 2-ethylbutanol [64]. The corresponding plasticizer, DHP (dihexylphthalate), has found application only in special cases. Commercial specifications are given in Table 4.

Hexanols have good solvent properties for fats and oils. Because of their lower volatility and higher viscosity, they are superior to pentanols in several applications, e.g., as flow improvers.

C_6–C_{10} Alcohol Mixtures. Condea [65] and the Ethyl Corp. [73] offer mixtures of C_6, C_8, and C_{10} alcohols under the trade names Alfol 610 and Epal 610, respectively. The 100 % linear alcohols are prepared by the Ziegler process (see Section 2.3.5). For the composition and typical data of alcohol mixtures with various C numbers, see Table 5.

The phthalates are suitable as plasticizers for coatings, artificial leather, poly(vinyl chloride) films and sheets, and anticorrosive pastes. The esters of aliphatic acids, also plasticizers, provide cable coverings, which are extremely resistant to cold, films, and artificial leather. They also find application in food wrapping.

Table 5. Composition and typical data of alcohol mixtures with various carbon numbers [65], [67], [73–76]

Manufacturer	Trade name	Chain-length distribution, wt % alcohol	Boiling range, °C	Density (20 °C), g/cm^3	n_D^{20}	Max. water content, wt %	*n*-Alcohol content, wt % (approx.)

* not available.

Mixtures of 1-hexanol and 1-octanol [*111-87-5*] serve as frothing agents (bubbling promoters) in flotation, e.g., of coal [77]. Large amounts are added to aqueous drilling muds to prevent frothing during drilling for oil and gas.

2.4.2. C_7 Alcohols

For physical properties see Table 1.

1-Heptanol [*111-70-6*] in its pure form has very little commercial value. It can be prepared from 1-hexene by oxo synthesis. Isomeric mixtures of various heptanols are of greater significance.

C_7 Alcohol Mixtures. Heptanol mixtures are prepared by the hydroformylation of isohexene, the dimerization product of propene. They have been used by Chisso and Nissan in Japan and also by Exxon for the manufacture of the phthalate plasticizer DIHP (diisoheptyl phthalate) or Jayflex 77, a fast-dissolving plasticizer with good low-temperature properties that is said to be particularly suited for poly(vinyl chloride) flooring and for use in plastisols [78].

C_7–C_{11} Alcohol Mixtures. From a linear $C_6/C_8/C_{10}$ olefin stream of the Ethyl Corp., Monsanto produces the corresponding alcohols with 7, 9, and 11 carbon atoms via oxo synthesis. Depending on the reaction conditions, the content of iso compounds is 30–35 %. In ad-

dition to $C_7/C_9/C_{11}$ mixtures, C_7/C_9 and C_{11} fractions also are available [74]. In the United States, practically the whole production is processed further to phthalates or adipates, used as plasticizers (trade name Santicizer).

Shell also produces mixtures of C_7, C_9, and C_{11} alcohols that are sold under the trade names Dobanal 91 (Europe) and Neodol 91 (United States, Canada). They are prepared by the Shell oxo process from linear olefins with internal double bonds and are ca. 80 % linear; corresponding product distributions are obtained by using α-olefins. The C_7/C_9 and C_9/C_{11} fractions are sold under the trade names Linevol 79 and Linevol 911 [75].

Imperial Chemical Industries (ICI) offers $C_7/C_8/C_9$ alcohol mixtures under the trade name Alphanol 79 [66]. Linopol 7 – 11, a mixture of $C_7/C_9/C_{11}$ primary and α-alkyl-branched alcohols with ca. 70 % *n*-isomer content, is produced by Kuhlmann [76].

Typical data for these mixtures as given in the various companies' data sheets are presented in Table 5. The mixtures are colorless liquids, miscible with most organic solvents but not with water.

Uses. Approximately 70 – 80 % are processed to plasticizers, mostly phthalates, which to a certain extent replace the plasticizer DOP, dioctyl phthalate, di-(2-ethylhexyl)phthalate, made from phthalic anhydride and 2-ethylhexanol (→ Plasticizers). However, DOP still commands the major share of the market.

These esters of dicarboxylic acids are used almost exclusively as plasticizers for PVC. The linear esters exhibit somewhat better low-temperature properties, greater resistance toward oxidation, and lower volatility than DOP. For example, in the United States the plasticizers Santicizer 711 (phthalate) and Santicizer 97 (adipate), manufactured by Monsanto from $C_7/C_9/C_{11}$ alcohol mixtures, have practically displaced DOP in automobile interiors because, owing to the lower volatility, no fogging of the windows takes place.

Further applications of the alcohols depend on their solvent properties. For alcohols with an odd number of carbon atoms, better solvent and wetting properties are claimed than for those with an even number [9], [68].

The alcohol mixtures are used as solvents or solubilizers in the paint and printing ink sector, as components in textile auxiliaries and pesticides, for hormone extraction, and in the surfactant field as foam boosters or antifrothing agents.

2.4.3. C_8 Alcohols

For physical properties see Table 1.

2-Ethyl-1-hexanol [*104-76-7*] is the most important C_8 alcohol (→ 2-Ethylhexanol).

$CH_3(CH_2)_3CH(C_2H_5)CH_2OH$

1-Octanol [*111-87-5*], $CH_3(CH_2)_6CH_2OH$, capryl alcohol. Its esters are widespread in nature; e.g., they occur in grapefruits, oranges, or green tea. 1-Octanol is manufactured by the Alfol process and from natural products. It is sold under the trade names Alfol 8, by Condea, and Lorol C 8, by Henkel. The alcohol is used, for example, in the perfume industry.

2-Octanol [*123-96-6*], $CH_3(CH_2)_5CH(OH)CH_3$, is obtained by the alkaline hydrolysis of castor oil. It is used as a solvent in the paint industry, as a wetting agent in the textile industry, and as a component of brake fluids.

C_8 Alcohol Mixtures (Isooctyl Alcohol). Butenes and propene are codimerized to heptenes which, in turn, are hydroformylated to mixtures of isomeric C_8 aldehydes. These are hydrogenated to yield mixtures of primary alcohols. In addition to 3,4-, 3,5-, and 4,5-dimethyl-1-hexanol and 3- and 5-methyl-1-heptanol, such mixtures contain varying amounts of heptanols and nonanols. They are colorless, slightly viscous, neutral liquids and have a mild fragrance. They are practically immiscible in water (0.06 wt % at 20 °C), but absorb up to 3.5 wt % water at 20 °C. They are miscible with most organic solvents. The mixtures are available under the names isooctanol or isooctyl alcohol from Ruhrchemie, Kuhlmann, ICI, Esso/Enjay, and UCC. The specifications of a typical commercial product are summarized in Table 4.

Isooctyl alcohol is an excellent solvent for many organic compounds, such as fats, oils, and waxes, as well as various rubber formulations

and resins. Isooctyl alcohol is especially suitable for baking enamels because, owing to its low vaporization tendency, cratering and blistering do not occur.

Further applications are as a foam suppressant, an extracting agent for metal salts (Mo, Re, Co) and mineral acids (e.g., phosphoric acid, boric acid from aqueous solutions), an emulsifier and stabilizer in oil emulsions, a modifier for PVC pastes, a polishing agent for acrylic ester polymers, and as a bath additive in galvanization.

Derivatives. As with all higher oxo alcohols, the principal use of isooctyl alcohol is as an esterification component in the preparation of plasticizers, mainly diisooctyl phthalate (DIOP), but also of esters of adipic, sebacic, azelaic, and trimellitic acids. Triisooctyl trimellitate, Jayflex 80-TM, is available from Exxon [78]. As a highly permanent monomeric plasticizer with low viscosity and low specific mass, it competes with polymeric plasticizers.

Various derivatives of isooctyl alcohol, for example, ethers or acetates are suitable as solvents for polymers. If metallic soaps are added, these products can be used as lubricating greases. Some esters are suitable as lubricants or hydraulic fluids.

For the preparation of surfactants, ethoxides or sulfuric acid esters of isooctyl alcohol are recommended. Organophosphorus derivatives, such as metal salts of diisoctyldithiophosphoric acid, are reported to be suitable as additives for lubricants, fuels, and hydraulic fluids.

In agriculture, the isooctyl esters of 2,4-dichloro- and 2,4,5-trichlorophenoxyacetic acid are used as nonvolatile herbicides.

C_8-C_{12} Alcohol Mixtures. Henkel supplies C_8/C_{10} and C_{10}/C_{18} alcohol fractions based on natural fats and oils under the names Lorol 810 and Lorol 818 [67]. The C_8/C_{10} fraction contains 3 – 8 % C_{12} alcohols (Table 5); Lorol 818 contains a wide range of C_8-C_{18} alcohols. Because alcohols from coconut and palm oils are available in only limited quantities, however, by far the greater portion of the alcohols in this range is derived from petrochemical sources. For example, Condea produces Alfol 810 and Alfol 1012 (C_8/C_{10} and C_{10}/C_{12} alcohol mixtures) from ethylene by the Ziegler process [65]. Similar products from the same feedstock are the Epal C_8/C_{10} and C_{10}/C_{12} fractions offered by the Ethyl Corp. [73].

The C_8/C_{10} and C_{10}/C_{12} alcohol mixtures, produced from natural products and by petrochemical methods, are both practically 100 % linear.

Mixtures of 1-octanol and 1-decanol are used by the tobacco industry as growth inhibitors [79].

Derivatives. Esters of aliphatic acids and of trimellitic acid with C_8-C_{10} alcohols are suitable as plasticizers for weather-resistant films and artificial leather as well as for special poly(vinyl chloride) applications, such as thermally stable cable coverings.

Upon addition of 3 – 6 mol ethylene oxide to C_8-C_{10} alcohols, ethoxides are obtained that possess some advantages over longer-chain detergents owing to their excellent solubility in water, improved viscosity, and especially good wettability. They are used as frothing agents in oil drilling, as components in gentle and low-temperature washing liquids, in technical cleansers, and also in the textile industry.

By sulfatation of the ethoxides the corresponding ether sulfates are produced, which possess high stability toward electrolytes and alkaline-earth metal ions. They are used as industrial foaming agents, e.g., for plaster and mortars, and for oil drilling. The sodium salts of alcohol sulfates are used to a slight extent as wetting agents with high stability towards electrolytes.

Primary alkylphosphates are prepared from the alcohols and phosphorus pentoxide. After neutralization with amines or alkali hydroxides, they are used as water-soluble anionic surfactants with high stability toward hydrolysis and as emulsifiers. Other derivatives of these alcohols, especially in the C_8-C_{10} range, include the corresponding amines. They are used for the solvent extraction of heavy metals, such as molybdenum, vanadium, uranium, and thorium, from acidic aqueous solutions. Quaternary ammonium salts with C_8-C_{12} alkyl groups are added to such cleaning agents as bactericides and fungicides.

Ether amines are obtained by cyanoethylation with acrylonitrile and subsequent hydrogenation (Sherex, Henkel). They are used as selective collectors for the flotation of silicates in low-quality iron ores.

2.4.4. C_9 Alcohols

For physical properties see Table 1.

C_9 Alcohol Mixtures. Nonanol mixtures are typical plasticizer alcohol components for the preparation of diisononylphthalate (DINP). Mixtures of C_9 alcohols are prepared by oxo synthesis from dimeric 1-butene and 2-butene (the mixture also is known as raffinate II) or from dimeric isobutene. Because of increased demand for isobutene for the production of methyl *tert*-butyl ether (MTBE), starting materials are now the relatively cheap mixed dimers of *n*-butenes and isobutene (codibutylenes) and dimers of *n*-butene in particular.

Typical commercial olefins of the latter variety are Dimersol from the IFP process and octenes from the UOP process (→ Hydrocarbons, Chap. 2.). Because of the differences in the manufacturing methods, these olefins have considerably different compositions, see Table 6. For specifications of the various alcohols obtained from them, see Table 7. The nonanol from diisobutene is the only one consisting primarily of 3,5,5-trimethyl-1-hexanol; the other alcohols are more or less complex alkyl-branched mixtures. Esso's isononyl alcohol, for example, contains 80 % dimethyl-1-heptanols and 20 % trimethyl-1-hexanol.

Derivatives. Isononyl alcohol is a useful high-boiling solvent for fats, oils, waxes, and resins. It is frequently used as a solvent in the paint industry. In nitrocellulose-based paints, it acts as a latent solvent; the addition of small amounts facilitates the blending with hydrocarbons. In paints based on alkyd resins, shellacs, or urea-formaldehyde resins the viscosity and the flow properties are improved; in baking enamels cratering and blistering are prevented.

As a rule, the mixtures immediately are processed further to plasticizers (for phthalates and esters of other dicarboxylic acids, → Plasticizers).

Isononyl esters of phosphorous, thiophosphorous, and dithiophosphoric acid are employed as additives for high-quality lubricants. The polyacrylates and polymethacrylates of isononyl alcohol are recommended for lowering the pour point temperatures of lubricating oils. They also are used as sealing liquids and hydraulic fluids, e.g., for vacuum and diffusion pumps.

Isononyl alcohol is the first in the series of oxo alcohols used for the industrial synthesis of surfactants. Neutralized isononyl sulfates or phosphates are wetting agents in the textile industry. Sodium diisononyl succinate is suitable as a wetting agent and as an emulsifier for various oils.

2,6-Dimethyl-4-heptanol [*108-82-7*] can be prepared by aldol condensation of acetone and subsequent hydrogenation.

$[(CH_3)_2CHCH_2]_2CHOH$

The alcohol is sold by UCC under the name diisobutylcarbinol. It is used as a reaction medium for the preparation of hydrogen peroxide and as an effective defoaming agent, in this case also in its ester form. The phosphates are extraction solvents for uranium and rare metals.

2.4.5. C_{10} Alcohols

For physical properties see Table 1.

1-Decanol [*112-30-1*], $CH_3(CH_2)_8CH_2OH$, is prepared by a number of producers, e.g., Henkel (Lorol C 10, Lorol C 10−98), by the catalytic reduction at high pressure of coconut oil or coconut fatty acids or esters. Greater, but still not significant quantities are manufactured by the Ziegler process. Companies offering the product include Conoco/Condea and the Ethyl Corp. The perfume industry uses 1-decanol as a raw material for detergents and as a defoaming agent.

C_{10} Alcohol Mixtures. Relatively complex, multi-branched mixtures of primary alcohols are manufactured almost exclusively by the hydroformylation of tripropylene. The main components of the mixture are isomeric trimethylheptanols and 3,5-dimethyloctanol. Isodecanol is sold by Hoechst, Kuhlmann, Esso, UCC, and ICI among others (Table 4).

The C_{10} alcohol mixtures are processed mainly to phthalate plasticizers (DIDP). Because of their low volatility and good low-temperature properties they are gaining steadily in importance for this application. Following

Table 6. Composition of various octenes (in wt %)

esterification with dicarboxylic acids, the C_{10} oxo alcohol mixtures yield synthetic ester oils with outstanding properties [1]. The C_{10} alcohol mixtures are also starting materials for a wide range of derivatives, which are employed as textile auxiliaries, stabilizers, flotation agents, and antifoaming agents, and are used in detergents, pharmaceuticals, cosmetics, and pesticides (esters with 2,4-dichloro- and 2,4,5-trichlorophenoxyacetic acid are herbicides).

2.4.6. Mixtures of Linear C_{12} – C_{18} Alcohols (Detergent Alcohols)

For more details → Fatty Alcohols.

n-Alcohols with carbon chain lengths of 12 to 18, in former times prepared solely from natural products and consequently known as fatty alcohols, are now also manufactured from ethylene by the Ziegler process and by the Shell version of the oxo process (*n*-alcohol content ca. 80 %). These alcohols are important intermediates for a large number of chemical products, but over 95 % of them are used in detergents (→ Surfactants).

To a lesser extent they are used directly as wetting, emulsifying, and foaming agents. For most applications, they are modified by insertion of a hydrophilic group, e.g., by ethoxylation with ethylene oxide to ethoxides, $RO(CH_2CH_2O)_nH$, by sulfatation of the ethoxides to the ether sulfates, e.g., $RO(CH_2CH_2O)_nCH_2CH_2OSO_3Na$, and by direct sulfatation to alcohol sulfates, $ROSO_3Na$.

The products prepared by esterification of the alcohols with acrylic or methacrylic acid and subsequent polymerization are employed mainly in lubricating oils as viscosity index improvers. The C_{12} – C_{15} region is preferred, but C_{16} – C_{18} alcohols also are used.

2.4.7. C_{13} – C_{18} Isoalcohols

Isotridecyl alcohol [*27458-92-0*] is prepared from tetrapropylene by oxo synthesis. The product isolated is actually a complex mixture of primary alcohols with an average of 13 carbon atoms.

Isotridecyl alcohol is a colorless, clear, slightly viscous, neutral liquid with a mild odor. It is manufactured by Hoechst, Kuhlmann, ICI, Esso, and UCC, and consists principally of tetramethyl-1-nonanols. A compilation of the standard specifications is given in Table 4.

Because of its extremely low volatility, the phthalate has special applications as a plasticizer in wire insulation based on PVC. The alcohol also is used as a surfactant raw material, as an antifrothing agent, and as a solvent where low volatility is required, e.g., for preventing cratering and blistering during the drying of paint surfaces.

Isohexadecyl alcohol [*36311-34-9*] is prepared by aldol condensation of isooctylaldehyde and subsequent hydrogenation of the isohexadecenal. A complex mixture of primary alcohols of 2,2-dialkyl-1-ethanols is obtained, wherein the alkyl groups consist of methyl-branched C_6 and C_8 units. The alcohol is manufactured by Esso and Shell.

Isohexadecyl alcohol is used in lubricants, e.g., as the esters of higher fatty acids, dicarboxylic acids, orthophosphoric acid, or unsaturated polybasic acids. Hexadecyl alcohol is also used as a component of detergents and wetting agents, textile aids, softeners, cosmetics, evaporation preventers, and foam breakers. In pure form it is applied as a flotation and extraction agent.

Isooctadecyl alcohol [*27458-93-1*] is a highly branched, primary C_{18} alcohol with 5,7,7-trimethyl-2-(1,3,3′-trimethylbutyl)-1-octanol [*36400-98-3*] as the main component. It is prepared by aldol condensation of isononylaldehyde and subsequent hydrogenation of the unsaturated aldehyde intermediate. It is a highly viscous, neutral, odorless liquid that is practically insoluble in and hydrophobic to water. The alcohol is miscibile with most organic liquids in all proportions.

The alcohol is available from Hoechst. As a highly branched alcohol it is suitable for many applications requiring a low pour point. It is used, therefore, for the manufacture of synthetic lubricants and hydraulic fluids. Because of the low vapor pressure, it is often applied to water surfaces to prevent evaporation (by formation of monomolecular layers).

Isostearyl alcohol is available from Mitsubishi Chem. under the name Diadol 18 G It is a slightly-branched alcohol with a definite structure (2-heptylundecanol) and is prepared either by the aldol condensation of nonanal or by the hydroformylation of a C_{17}-vinylidene olefin. It is used as the waxy component for high-quality cosmetics.

2.5. Economic Aspects

The economic significance of alcohols can be seen clearly from the production figures (in 10^6 t, 1980):

Methanol	12.0
C_6-C_{11} Alcohols	2.0
Ethanol	≈ 4.0
$C_{12}-C_{15}$ Alcohols	0.6
C_3-C_7 Alcohols	2.0
$C_{16}-C_{18}$ Alcohols	0.4

Crude oil and natural gas still predominate as raw materials for their manufacture. However, the oil crisis in the 1970s induced a number of countries to develop coal and natural materials as a substitute. For example, production of ethanol by fermentation or from $C_{16}-C_{18}$ alcohols from fats and oils should increase worldwide.

As a result of the development of new competitive gasification processes, coal is expected to be used increasingly as raw material for the production of synthesis gas from which methanol and C_3-C_{15} alcohols can be made [80]. Table 8 gives a survey of the basic raw materials for higher alcohols. About 90 % of these alcohols are produced from petrochemicals.

About two thirds of the higher alcohols can be classified as plasticizers (C_6-C_{11}) and one third as detergents ($C_{12}-C_{18}$).

Plasticizer Alcohols (C_6-C_{11} and C_{13}-Branched Alcohols). Table 9 shows the 1980 consumption, actual production, and production capacities of plasticizer alcohols in the major Western industrial countries. About 75 % of the available production capacity was being utilized; 85 % of the alcohols produced were consumed in the producer countries, and about 15 % were exported, especially to East Asia. With a near 60 % share of the market, 2-ethylhexanol is the most important plasticizer alcohol. Insufficient production capacity (USA) and an unfavorable raw material supply (Japan) have led to shortages in these countries. Therefore the other C_6-C_{11} alcohols have gained in significance, particularly in the United States. An outline of

Table 8. World capacity of C_6-C_{18} alcohols, 1980 (10^3 t)

	C_6-C_{11} Alcohols	$C_{12}-C_{15}$ Alcohols	$C_{16}-C_{18}$ Alcohols	Total	%

the C_6-C_{11} alcohol producers in 1980 with capacity and process type is given in [81].

Table 10 contains a list of the plasticizer alcohols produced in Western Europe, the United States, and Japan in 1980, classified according to process and raw material source. Table 11 shows the relative market shares of various plasticizer alcohols and alcohol mixtures.

With plasticizer alcohols the term "linear" has a different meaning; alcohols from the oxo synthesis are customarily termed linear even if, depending on the process variant, they contain 20–50 % α-alkyl-branched isomers mixed with the *n*-alcohol components. In the strict sense of the word, therefore, only the alcohols from the Ziegler process (5 %) and on the basis of natural raw materials (1 %) can be termed "linear."

Future Aspects. The further development of plasticizer alcohols and the phthalates produced from them is closely connected with the development of PVC, as up to 50 % phthalate is mixed with the polymer. In the Western industrial countries relatively small growth rates are expected.

The following key developments will have an influence on the relative market shares of the different alcohols [1], [82]:

1) The changes in the costs of raw materials. This favors *n*-butene (dimersol) as a feedstock to the detriment of ethylene.
2) The shrinking market for linear phthalates and the trend toward "softer" vinyls favors DIDP.
3) The trend toward plasticizers of higher quality than DOP (fogging problem in automobile furnishings and vinyl roofing) will lead to a shift from 2-ethylhexanol and isooctyl alcohol toward higher alcohols.
4) The trend toward a reduction of the processing temperature in the manufacture of PVC products and toward the use of extra fillers.
5) More stringent environmental regulations during processing (volatility of plasticizers) is promoting the trend toward less volatile plasticizers.

Detergent Alcohols ($C_{12}-C_{18}$). The following figures show the relative worldwide feedstocks for $C_{12}-C_{18}$ alcohols [18]:

	$C_{12}-C_{15}$	$C_{16}-C_{18}$
Petrochemical (%)	83	40
Natural (%)	17	60

Because most of the natural oils and fats (tallow) consist almost entirely of $C_{16}-C_{18}$ fatty acids, which are available in large quantities [18], [83], [84], their significance as raw materials will increase in the years to come, a trend that also will be promoted by the price increase of natural and petrochemical raw materials [80]. On the other hand, the possibilities of using natural raw materials in the $C_{12}-C_{15}$ range are limited because the corresponding lauric oils only make up about 5 – 7 % of world oil and fat production (1980: 3.3×10^6 t) [85] and are mostly used in the food industry. Therefore this range is produced primarily from petrochemical feedstocks.

In 1980, when the total production capacity for surfactant alcohols in the Western World was about 911000 t [86], only 516000 t actually were produced. For producers, process type, and installed capacities in the Western World, see [86]. The relative production figures % for the different processes are:

Oxo process	41 %
Ziegler process	21 %
Natural basis	35 %
Paraffin oxidation	3 %

Consumption figures for the surfactant alcohols and their derivatives are given in Table 12.

Future Aspects. A large growth in the production of surfactant alcohols is expected in the next few years [87] owing to the increasing demand for non-ionic detergents, which exhibit good washing properties even in low-phosphate detergent formulations (environmental regulations). In view of the limited supplies of $C_{12}-C_{15}$ raw materials and the uncertainty in the price development of lauric oils [88], there will be a continued increase of the quantities in this range produced on a petrochemical basis. The natural raw materials otherwise will increase their share in the production of $C_{15}-C_{18}$ alcohols; for corresponding data see [26].

Table 12. Consumption of detergent alcohols, 1980 (10^3 t)

2.6. Quality Specifications

The quality control specifications for alcohols are given by DIN [89] or ASTM [90]; analytical procedures are compiled by the Deutsche Gesellschaft für Fettwissenschaft [91] and by Henkel [3]; see also [2].

The most important analytical procedure by far is *gas chromatography*. Chain-length distribution, the proportion of unsaturated, branched, or secondary alcohols, as well as small amounts of esters and hydrocarbons can be determined using suitable columns and conditions.

An important quality criterion for alcohols is the *carbonyl number,* which indicates the degree of impurity caused by carbonyl compounds. It is determined by titration of the hydrochloric acid released by reaction of the carbonyl groups with excess $NH_2OH \cdot HCl$. Its numerical value expresses the mass of CO (mg) in the form of carbonyl groups, that are present in 1 g of product.

The *hydroxyl value* (HV=mg of KOH equivalent to the hydroxyl content of 1 g of alcohol) measures the hydroxyl groups and reflects both the molecular mass and the purity of the sample.

The *saponification number* is the number of mg KOH that is required to neutralize the acids and saponify the esters contained in 1 g of substance. The *iodine value* (g of iodine consumed by 100 g of alcohol) is a measure of the content of unsaturated compounds. The *water content* is determined by the Karl Fischer method [3]. The *color* of the alcohol is usually given in Hazen units (the mass of platinum (mg) present in a solution of K_2PtCl_6 and $CoCl_2 \cdot 6\,H_2O$ in a mass ratio of 1 : 0.8025 in 1000 ml aqueous HCl that has the same color as the alcohol). Hazen numbers of 5 to 10 should not be exceeded.

A number of other tests relating to smell, melting point, boiling range, and color stability also serve as indications of quality and storage stability. One special test is, e.g., the color determination after treatment with concentrated sulfuric acid or after saponification with phthalic acid in the presence of sulfuric acid.

The recognition of the *source* of alcohols and alcohol mixtures (natural, Ziegler, oxo, paraffin oxidation, etc.) is summarized in [92]. A further valuable aid is ^{13}C NMR spectroscopy [93]. Using this technique, it is even possible to identify alcohol fractions from several different feedstock sources [3].

The *heavy-metal content* of alcohols should not exceed 1×10^{-6} g/g because of catalytic effects (reduced storage stability).

How pure an alcohol should be and what impurities it may contain usually depend on the further processing requirements and subsequent application. The specifications usually are agreed upon individually by the manufacturer and customer; therefore, alcohols of differing qualities are obtainable from the same producer.

2.7. Storage and Transportation

Short-chain liquid alcohols can be stored in containers made of noncorroding unalloyed carbon steel or stainless steel. Aluminum containers also are suitable, but not for long-term storage of lower alcohols. For higher alcohols, containers of pure aluminum and frequently of Al-Mg-Mn alloy (DIN 1725/1745) are used. Stainless steel is necessary only for the storage of extremely water-free alcohols. In aluminum vessels, corrosion is to be expected because of the formation of aluminum alkoxides. The storage temperature should be as low as possible.

In order to avoid oxidation, an inert-gas unit should be installed to enable flushing with pure nitrogen, etc. Water content of ca. 0.1 % has a

stabilizing effect; for extremely water-free alcohols the danger of autoxidation is very great.

Liquid alcohols are transported in painted, corrugated iron vessels, in road tankers, or in tank wagons made of normal steel, aluminum, or stainless steel. Solid products, such as the higher alcohols, are sold as flakes contained in multilayer polyethylene-lined paper bags.

Transportation is controlled by a number of general instructions and legal regulations for volatile and flammable substances.

The alcohols are classified on the basis of their specific properties, such as flash point, boiling point, etc.

3. Unsaturated Alcohols

Compared with saturated alcohols, unsaturated ones are of minor importance. In the United States the consumption of allyl alcohol, the most important unsaturated alcohol (→ Allyl Compounds), amounted to 60000 t in 1979. The proportion attributed to the other unsaturated alcohols, which are prepared in processes based either on acetylene or on natural feedstocks, is even smaller.

The unsaturated alcohols are generally colorless, pungent-smelling liquids and even 9-*trans*-octadecenol has a melting point of only 37 °C. The solubility in polar solvents, especially of the lower members, is high.

Some physical properties of unsaturated alcohols are given in Table 13. The accumulation of several functional groups in the molecule leads to a high reactivity. Therefore, they are capable of undergoing a large number of chemical reactions and frequently serve as intermediates in the chemical industry.

Table 13. Physical properties of unsaturated alcohols

Name		Formula	M_r	*mp*, °C	*bp*, °C	d_4^{20}	n_D^{20}

Crotyl Alcohol [*6617-91-5*], 2-buten-1-ol, $CH_3CH{=}CHCH_2OH$, is made by aldol condensation of acetaldehyde and subsequent hydrogenation. It is of little industrial importance since butanol has been manufactured via the oxo synthesis rather than from crotonaldehyde.

Propargyl Alcohol [*107-19-7*], 2-propyn-1-ol, $HC{\equiv}C\text{-}CH_2OH$, is formed as a byproduct ($\sim$ 5 %) in the butynediol synthesis from acetylene and formaldehyde [94] ($\rightarrow$ Butanediols, Butenediol, and Butynediol):

Copper acetylide serves as catalyst. The reaction can be controlled in such a way that either propargyl alcohol (high acetylene pressure, low formaldehyde concentration) or 2-butyne-1,4-diol (excess formaldehyde) is formed preferentially.

Main manufacturers using this process are BASF, GAF, Du Pont, and GAF/Chemische Werke Hüls. Total capacity for butanediol from butynediol has increased since 1975 from 70000 t/a to over 280000 t/a, so that the total capacity of propargyl alcohol is ca. 14000 t/a in 1980.

The alcohol is an excellent rust inhibitor, superior in this respect to allyl alcohol. It retains its rust-inhibiting properties at high temperatures and therefore is used for oil drilling.

Methylbutynol, 2-methyl-3-butyn-2-ol, [*115-19-5*], $HC{\equiv}C\text{-}C(CH_3)_2OH$, is formed by the ethynylation of acetone in base. Since 1977 it has been used as an intermediate for the manufacture of isoprene. Further applications are the preparation of vitamin A and other products and use in metal pickling and plating operations.

Oleyl Alcohol, *cis*-9-octadecen-1-ol, [*143-28-2*], $CH_3(CH_2)_7CH{=}CH(CH_2)_7CH_2OH$, is the most important natural-based unsaturated alcohol. All commercial fatty alcohols derived from natural sources contain oleyl alcohol to a greater or lesser extent. It is prepared by catalytic hydrogenation under pressure of the methyl esters of unsaturated fatty acids; mixed catalysts containing zinc are employed, and the reaction conditions correspond to those for the production of saturated fatty alcohols [95]. The methyl esters of the fatty acids are prepared from beef tallow and olive oil.

Oleyl alcohol is sold by Henkel under the trade name HD-Ocenol. Other manufacturers are New Japan Chemical Co., Ashland Chem. Co., and Kedzierzyn, Poland. Total capacity amounts to ca. 35000 t/a. The alcohol is used principally in the detergent field, where the double bond offers possibilities for applications not covered by the saturated fatty alcohols.

4. Alkoxides

Metal alkoxides can be formally regarded as salts of very weak acids (J. Liebig, 1837).

The alkoxides of alkali metals, magnesium, aluminum, titanium, zirconium, and antimony are commercially the most important ones, e.g., as catalysts in condensation and transesterification reactions, as reducing agents, and as paint additives.

4.1. Properties

The properties of the alkoxides depend on the position of the metal in the periodic table and on the character of the alcohol component. The alkoxides of the highly electropositive metals are solid, nonvolatile, very basic compounds of ionic nature. Polymeric, covalent compounds with a low volatility are formed by the higher multivalent elements; the alkoxides of the lighter transition elements are distillable, monomeric, covalent liquids. The alkali and alkaline-earth metal alkoxides are soluble in organic solvents to only a limited extent owing to their polar nature. Alkali-metal alkoxides crystallize from alcohol solution mostly with 1 – 3 mol alcohol (crystal alcohol), which can be removed by raising the temperature or by azeotropic distillation with benzene or toluene [96]. Heating to above 200 °C generally leads to decomposition [96]. The lower alkoxides of aluminum (with the exception of methoxide) and titanium can be distilled in the vacuum without decomposition. The physical properties of metal alkoxides have been discussed in detail, cf. [96–98].

Alkoxides are very reactive toward compounds having acidic hydrogen atoms, for example, with water:

$$ROM + H_2O \rightleftharpoons ROH + MOH$$

Therefore, alkoxides are stable only in the absence of water. With highly electropositive metals the reaction is reversible so that, e.g., the sodium ethoxide can be obtained from sodium hydroxide and ethanol. With the covalent multivalent alkoxides, however, this reaction is irreversible. The hydrolysis of titanium and aluminum alkoxides has been examined thoroughly [98]. With other alcohols transalcoholization occurs until equilibrium is established:

$$ROM + R'OH \rightleftharpoons R'OM + ROH$$

In this way the alkoxides of higher alcohols can be obtained from lower alkoxides. Reaction with phenol leads to the phenoxides:

$$M(OR)_n + n\,C_6H_5OH \longrightarrow M(OC_6H_5)_n + n\,ROH$$

By reaction with carboxylic acids, the metal salts of the carboxylic acids and the free alcohols are formed:

$$M(OR)_n + n\,R'COOH \longrightarrow M(R'COO)_n + n\,ROH$$

Reaction of trialkyl silanols with alkoxides gives the corresponding trialkylsiloxy metal derivatives [99]:

$$M(OR)_n + n\,R'_3SiOH \longrightarrow M(OSiR'_3)_n + n\,ROH$$

β-Dicarbonyl compounds form chelate complexes with alkoxides.

The alkoxides react with carbonyl compounds in different ways depending on their basicity. With alkali-metal alkoxides enolization or condensation reactions occur. The Tishchenko reaction with aluminum alcoholates leads to esters by disproportionation [100]:

$$2\,RCHO \xrightarrow{Al(OR)_3} RCOOCH_2R$$

In the Meerwein–Ponndorf–Verley reaction, ketones are reduced with alcohols in the presence of aluminum triisopropoxide:

$$R\text{–}CO\text{–}R + R'_2CHOH \rightleftharpoons R_2CHOH + R'\text{–}CO\text{–}R'$$

Transesterification reactions of esters with alkoxides also are known [101]:

$$M(OR)_n + n\,R''COOR' \rightleftharpoons M(OR')_n + n\,R''COOR$$

Other alkoxides catalyze transesterification reactions; e.g., benzoic acid butyl ester and ethanol are obtained from benzoic acid ethyl ester and butanol in the presence of titanium isopropoxide [*546-68-9*] [102]. A detailed description of reactions and applications of alkali and alkaline-earth metal alkoxides has been published [103].

4.2. Preparation

Alkoxides may be obtained by the reaction of alcohols with metals, metal hydroxides, metal halides, or alkoxides of other alcohols; the method depends on the metal and the alcohol component. A summary of the procedures can be found in [96].

Preparation from Metals and Alcohols.

$$M + n\,ROH \longrightarrow M(OR)_n + n/2\,H_2$$

This reaction is the simplest method for the preparation of alkoxides; it is limited to the alkali metals and to magnesium and aluminum. The alkali metals are suspended in an inert solvent [104] or are used as an amalgam [105]. The amalgam is brought into contact with the alcohol in a packed column according to the countercurrent principle. A graphite or Fe–Cr–C alloy contact electrode that cannot be amalgamated is used to speed up the reaction [106]. The longer the alcohol chain, the less vigorous the reaction. Primary alcohols react fastest, tertiary slowest. Magnesium and aluminum must be activated by the addition of catalysts, e.g., mercury chloride, HCl, or iodine [107]. Other catalysts, especially for magnesium, are *p*-toluenesulfonic acid and orthoformic acid esters [108]. By heating the alcohols in a column filled with aluminum turnings, the corresponding aluminum alkoxides can be produced without the aid of a catalyst [109].

Reaction of Alcohols with Metal Hydroxides. The equilibrium reaction of alcohols with metal hydroxides can be driven to completion by azeotropic distillation of the water formed with benzene, toluene, or the alcohol itself [110].

$$n\,ROH + M(OH)_n \rightleftharpoons M(OR)_n + n\,H_2O$$

The method is suitable only for the highly electropositive elements; lithium hydroxide does not react [111].

Reaction of Alcohols with Metal Halides. For the alkoxides of the less electropositive elements the corresponding metal chlorides are reacted with the alcohols:

$$MCl_n + n\,ROH \rightleftharpoons M(OR)_n + n\,HCl$$

The process is primarily suitable for the production of alkoxides of multivalent metals, such as titanium, germanium, and antimony. Mixtures with chloroalkoxides always are obtained. Bases, in particular ammonia, are used to shift the equilibrium toward the formation of pure alkoxides:

$$TiCl_4 + 2\,ROH \rightleftharpoons TiCl_2(OR)_2 + 2\,HCl$$

$$TiCl_2(OR)_2 + 2\,ROH + 2\,NH_3 \rightleftharpoons Ti(OR)_4 + 2\,NH_4Cl$$

Reaction of Metal Alkoxides with Metal Halides and Other Metal Compounds. In particular the alkoxides of multivalent metals can be prepared from their halides (MX_n) by reaction with other alkoxides (preferably of monovalent metals):

$$MX_n + n\,MOR \rightleftharpoons M(OR)_n + n\,MX$$

Nearly all metal alkoxides can be manufactured by this process. Sometimes other metal compounds are employed instead of halides; see [103] for details.

Reaction with Other Alkoxides. The alkoxides of higher or multivalent alcohols also can be prepared by alcohol transfer:

$$n\,R'OH + M(OR)_n \rightleftharpoons (R'O)_nM + n\,ROH$$

The more volatile alcohol distills from the reaction mixture [112]. However, when a large excess of the lower alcohol is used, a lower alkoxide can be obtained from a higher one.

4.3. Uses

Alkoxides of alkali metals are used predominantly as condensation agents in organic synthesis and to introduce the alkoxy group into other compounds. The methoxides and ethoxides of sodium and potassium and the potassium *tert*-butoxide have attained particular significance. For the use of sodium ethoxides, see [103], [113], [114]. Magnesium alkoxides are used as raw materials for driers in paints and varnishes and as components of highly active Ziegler catalysts [115]. Aluminum isopropoxide and aluminum *sec*-butoxide are used commercially as specific reducing agents for various organic compounds (Meerwein-Ponndorf-Verley reaction,see Section 4.1). They also find application in paints to improve resistance to chemicals [116], in textiles to produce impregnating agents, and in cosmetics as components of antiperspirants.

Titanium alkoxides are used in the manufacture of corrosion-proof, high-temperature paints, as esterification catalysts, for the water proofing of textiles, as bonding agents in adhesives, and as catalyst components for the polymerization of olefins.

Besides the solid alkoxides, solutions in the corresponding alcohols are on the market. Alkoxides are very easily hydrolyzed by water, extremely easily in the case of the short-chain alkoxides. Contact with atmospheric moisture must be avoided because spontaneous ignition may occur. Alkoxide fires must be extinguished with dry sand or powder but never with water.

Solid alkoxides are sold mostly in polyethylene bags packed in drums or in corrugated barrels fitted with special lids. Alkoxide solutions, e.g., the 25 % solution of sodium methoxide in methanol, however, also are transported in tankers. During unloading, a dry, inert-gas atmosphere must be provided.

Compared with alcohols, the alkoxides are of minor commercial importance. The 1982 world production is estimated at 10000–12000 t.

5. Toxicology

1-Hexanol. The oral LD_{50} is 4.87 g/kg for rats [117] and 4.0 g/kg for mice [118]. The maximum nonlethal period of time that rats can inhale a saturated atmosphere is 8 h [119].

1-Hexanol is a severe irritant to the rabbit eye [119]. It is moderately irritating to the skin of rabbits after 24-h skin contact [120]. The dermal LD_{50} is 2.53 g/kg, an indication of considerable dermal absorption [119]. 1-Hexanol is not a human skin irritant according to the Epstein test [121]. Also, it does not act as a skin sensitizer [122].

2-Methyl-1-pentanol. The oral LD_{50} for rats is reported to be 1.41 g/kg. For rabbits the dermal LD_{50} is 3.56 g/kg. In the open-patch test, 2-methyl-1-pentanol caused mild skin irritation in rabbits. In humans, inhalation of 50 ppm irritates mucous membranes [123].

4-Methyl-2-pentanol. The oral LD_{50} for rats is 2.59 g/kg [119]. Symptoms of acute intoxication are anesthesia, gastrointestinal irritation, and congestion of the mesenteric blood vessels [119].

In the rabbit eye, 4-methyl-2-pentanol was found to be a mild irritant [119]; after prolonged exposure corneal lesions can occur [124]. The skin irritation is reported to be mild [79], but absorption is considerable. Repeated exposure causes severe drying of the skin due to degreasing [125].

Mice that had inhaled concentrations of 4600 ppm for 1 min showed irritated respiratory passages, drowsiness, and anesthesia; after 10 min, death occurred occasionally, and after 15 min, 8 out of 10 mice had died [125]. For humans, eye irritation is reported after an exposure to 50 ppm for 15 min; more than 50 ppm causes irritation of nose and throat. Exposure to 25 ppm does not cause symptoms to appear [126]; therefore, the TLV and MAK values are set at 25 ppm.

2-Octanol. The oral LD_{50} is 3.2 g/kg for rats [127] and 4.0 g/kg for mice [118]. Rabbit eyes develop a pronounced redness on contact with 2-octanol [118]. In guinea pigs, 2-octanol is a slight skin irritant [128]. Rats were exposed for 4.5 months to a maximum inhalation concentration of 56.3 ppm for 2 h/day, 6 days/week. Hematological changes (anemia) and changes in liver metabolism, kidneys, and myocard were observed [128].

C_9 Alcohol Mixtures. Oral LD_{50} for rats range from 2.98 g/kg [129] to 6.4 g/kg [130]. Percutaneous LD_{50} fall in a similar range [131]. Inhalation of 21.7 mg/L for 4 h causes death in rats [129]. Eye contact causes conjunctivitis and keratitis in rabbits. Inhalation of 33, 99, and 136 ppm by rabbits for 2 months caused degenerations of glial cells in the cerebral cortex and subcortex [132].

C_{10} Alcohol Mixtures (Decyl Alcohols). LD_{50} values differ considerably because of the variable composition of the mixtures. After oral administration to rats the values range from 4.72 g/kg [129] to 25.6 g/kg [130]. Dermal LD_{50} for rabbits are reported to be between 3.56 mL/kg and 18.8 mL/kg [133]. The inhalative LD_{50} for mice is 525 ppm [132].

Eye contact in rabbits causes severe irritative conjunctivitis with corneal injuries [129]. Skin contact in guinea pigs [130] and rabbits [129] for 24 h causes moderate to severe skin irritation.

In a 60-week skin painting study in mice, *n*-decanol showed tumor promoting activities in the presence of dimethylbenzanthracene initiator; however, these concentrations of *n*-decanol alone irritated the skin considerably [134].

1. General Aspects

The properties common to all polyhydric alcohols are determined by the hydroxyl groups: hydrogen bonding leads to high boiling points, high viscosity, and solvency for polar substances. Other important characteristics are the structure of the alcohols and the accessibility of the hydroxyl groups (primary, secondary, or tertiary), which influence the chemical behavior and the thermal stability of the hydroxyl functions. Alcohol groups next to a *neo* structure (e.g., pentaerythritol or neopentyl glycol) exhibit higher resistance towards elimination and degradation because of the lack of β-hydrogen atoms. Some of the important physical properties of the alcohols discussed in this article are given in Table 1.

Important reactions of polyhydric alcohols are those with isocyanates to form urethanes, with acids and acid anhydrides to form esters, and with aldehydes or ketones to form acetals or ketals.

Polyhydric alcohols, especially triols and tetrols, are normally regarded as polyols, but in the literature poly(ether alcohol)s such as poly(ethylene glycol)s and/or poly(ester alcohol)s are sometimes also classified as polyols.

Production. Each class of polyhydric alcohol has its own basic production method and raw materials. The most important synthetic strategies are presented in Scheme 1.

The reactions can be classified into the following general categories:

a) Epoxidation of alkenes followed by acid-catalyzed cleavage of the epoxide ring to obtain the 1,2-diol.

Scheme 1. Synthetic routes to polyhydric alcohols

b) Base-catalyzed aldol addition of formaldehyde to the appropriate higher aldehyde, followed by reduction, either by Cannizzaro reaction with excess formaldehyde and base or by catalytic hydrogenation. Reduction by the Cannizzaro reaction causes the formation of large amounts of formate salt, so that several recrystallization steps are required for the separation of the salts from the products. For the catalytic hydrogenation to be worthwhile, the equilibrium of the aldol addition must lie sufficiently to the right, that is, sufficient β-hydroxyaldehyde must be formed in the first step.
c) Addition of water to α,β-unsaturated aldehydes also results in formation of β-hydroxyaldehydes. The corresponding 1,3-diol can be obtained by subsequent hydrogenation.
d) Hydroformylation of epoxides represents the third method for producing β-hydroxyaldehydes for hydrogenation to 1,3-diols. In contrast to the aldol method (b), the methods based on Michael addition of water (c) and the cleavage of epoxides (a) are limited to the generation of one 1,3-diol unit.
e) Addition of aldehydes or ketones to acetylene to give the alkynediols or the corresponding 1,4-diols by subsequent hydrogenation.
f) Catalytic hydrogenation of carboxylic acids and their esters.
g) Hydrogenation of phenols or phenol derivatives (e.g., bisphenol A).

Uses. The chief use of polyhydric alcohols is as components of saturated and unsaturated polyester resins and alkyd resins. These resins, which are known for their excellent stability, are used in a wide range of varnishes and coatings. The addition of polyisocyanates to polyetherpolyols and polyesterpolyols derived from polyhydric alcohols leads to polyurethanes, which are used for the production of elastomers and various types of foams. Other uses are as synthetic lubricants, plasticizers, dispersants, fibers, and as additives to poly(vinyl chloride). Some of the diols are used in the production of pharmaceuticals and fragrances.

2. Diols

2.1. 1,5-Pentanediol

1,5-Pentanediol [*111-29-5*], pentamethylene glycol, $HOCH_2(CH_2)_3CH_2OH$, is a colorless liquid (see Table 1), soluble in water, alcohol, acetone, and relatively insoluble in aliphatic and aromatic hydrocarbons.

Production. 1,5-Pentanediol usually is produced by catalytic hydrogenation of glutaric acid or of its esters, although dicarboxylic acid mixtures containing glutaric acid also may be used (see Section 2.3). The crude products are purified by distillation. Manufacturers of 1,5-pentanediol are BASF and Ube Ind.; the world capacity is about 500 t/a.

Uses. 1,5-Pentanediol is the starting material for the production of various heterocyclic compounds, such as 1-methylpiperidine, which are used in the synthesis of pharmaceuticals and pesticides. The substance is also used in the production of fragrances and as a component of polyesters and polyurethanes.

2.2. 1,3-Propanediols

2.2.1. 2,2-Dimethyl-1,3-propanediol (Neopentyl Glycol)

Neopentyl glycol [*126-30-7*] has become an industrially important and versatile diol [1], particularly as a building block for polyesters and polyurethanes.

$HOCH_2C(CH_3)_2CH_2OH$

This is because of the wide availability of the starting materials, isobutyraldehyde and formaldehyde, and the extraordinary stability of its derivatives resulting from the quaternary structure and the absence of hydrogen atoms in the β-position.

Physical Properties. Neopentyl glycol (see Table 1), colorless crystals, has a phase transition at 40 – 42 °C. It is hygroscopic at

relative humidities greater than 50 % and sublimes readily, even somewhat below the melting point. Neopentyl glycol is soluble in water, alcohols, and ketones, moderately soluble in hot aromatic solvents, such as benzene and toluene, and relatively insoluble in aliphatic and cycloaliphatic solvents.

Chemical Properties. Pure neopentyl glycol is thermally stable up to the boiling point. However, in the presence of alkali salts or bases, neopentyl glycol decomposes above 140 °C.

In addition to the reactions typical of primary alcohols, such as ester, ether, and carbamate formation, 1,3-diols give six-membered cyclic derivatives with carbonyl compounds, carbonates, phosphites, sulfites, and borates.

Production. The aldol addition of isobutyraldehyde (2-methylpropanal) and formaldehyde gives hydroxypivaldehyde (3-hydroxy-2,2-dimethylpropanal) [*597-31-9*], which is then reduced to neopentyl glycol:

Both aldol addition and subsequent reduction are exothermic. Hydroxypivaldehyde can be reduced either by a crossed Cannizzaro reaction with equimolar amounts of formaldehyde and a base, or by catalytic hydrogenation (see Scheme 1).

Production by the Cannizzaro Reaction. In this process, aldol addition and reduction can be performed either simultaneously [2] or in two stages [3]. However, the individual reactions can be controlled more selectively in the two-stage process. Reduction of hydroxypivaldehyde with formaldehyde/sodium hydroxide solution leads to the coproduction of 0.8 – 0.9 t sodium formate per tonne of neopentyl glycol and to high production costs. The sodium formate has a limited commercial value.

Production by Catalytic Hydrogenation. This process usually is performed in two stages. The type of catalysts used for the aldol addition has a significant effect on the technical requirements of the hydrogenation and purification stages.

If *inorganic bases* such as potassium carbonate [4] or sodium hydroxide [5], [6] are used as catalysts, satisfactory yields (ca. 80 %) of neopentyl glycol can be obtained only with an excess of isobutyraldehyde. Side products formed by aldol addition, Cannizzaro reactions, or Tishchenko reactions are 2,2,4-trimethyl-1,3-pentanediol, neopentyl glycol isobutyrate, and hydroxypivalic acid neopentyl glycol ester (Section 2.2.2). Salts are also formed which interfere with the hydrogenation catalyst or cause decomposition during distillation. Sodium hydroxide always gives some Cannizzaro reaction, which can be partially suppressed by excess isobutyraldehyde and/or water soluble solvents such as aliphatic alcohols [6].

Hydroxypivaldehyde is separated from salts by extraction with dibutylether and hydrogenated on copper chromite catalyst between 175 and 220 °C.

In a variant of this process [7] hydrogenation and hydrogenolysis are performed stepwise at different temperatures (120 – 160 °C and 175 – 190 °C). At the higher temperature, ester byproducts also are hydrogenated to the corresponding alcohols.

Ruhrchemie [8] has avoided the interference of alkali salts, formed during the aldol addition, in the hydrogenation and in the purification stages by diluting the hydroxypivaldehyde with isobutanol, evaporating the mixture, and then hydrogenating the hydroxypivaldehyde in the gas phase at 110 – 150 °C over cobalt, copper, or nickel catalysts.

Tertiary amines are the state-of-the-art catalysts for the aldol addition.[9]. Hydroxypivaldehyde is formed rapidly by the reaction of isobutyraldehyde (up to 10 % excess), formaldehyde, and trialkylamine. The reaction is characterized by the complete conversion of formaldehyde, which is the main difference to the classical processes for trimethylolpropane and pentaerythritol. The excess of isobutyraldehyde is distilled and recycled together with the amine. The reaction runs very selectively and therefore most of the side products which are typical of the production based on the Cannizzaro reaction are negligible. The conditions of the hydrogenation reaction vary from 80 to 200 °C and 35 – 300 bar. Heterogeneous catalysts based on cobalt, cop-

per, or nickel can be used in the fixed-bed reactor [10]. After fractional distillation a very good yield of high-purity neopentyl glycol is obtained.

Quality, Storage, and Transportation. Commercial neopentyl glycol has a purity of about 99 % (determination by GLC). Impurities may include neopentyl glycol monoformate, neofpentyl glycol monoisobutyrate, 2,2,4-trimethyl-1,3-pentanediol, and the cyclic acetal from the reaction of hydroxypivaldehyde and neopentyl glycol.

During storage, higher temperatures and stacking pressures can lead to caking of the lower stack layers. As a hygroscopic material, neopentyl glycol must be stored dry.

Producers. Manufacturers are: BASF, Hoechst Celanese, Degussa-Hüls, Eastman Kodak, Koei, Mitsubishi Gas Chemical, Perstorp, and Polioli. World capacity is estimated at about 220 000 t/a.

Uses. The main use of neopentyl glycol is in saturated polyester resins for coil coatings and internal coating of tins, packing material varnishes, car varnishes, electrical insulation, and wire coatings, as well as in alkyd resins for paint varnishes, household varnishes, and self-drying industrial and ship varnishes. The alkyd resins can be used as solvent-containing, radiation-cured, water-dilutable, and powder varnishes and as high-solids paints. Neopentyl glycol is gaining importance particularly as a diol component in powder coating systems. In addition to the technological advantages of these varnishes, they are highly stable with respect to hydrolysis, to attack by alkali, and to heat; they also are weather-resistant.

Neopentyl glycol imparts the same advantages to unsaturated polyester resins, which are used for gel coats, corrosion resistant containers, and in molding materials for building components, etc. In addition, neopentyl glycol is a component of polyesterpolyols in plasticizers, its esters are synthetic lubricants, it is used as dispersant for titanium dioxide, and as starting material for polyurethanes.

2.2.2. Hydroxypivalic Acid Neopentyl Glycol Ester [11]

Hydroxypivalic acid neopentyl glycol ester, (3-hydroxy-2,2-dimethylpropyl)-3-hydroxy-2,2-dimethylpropionate (HPN) [*1115-20-4*] is the monohydroxypivalate of neopentyl glycol:

The compound has properties similar to neopentyl glycol but in addition specific characteristics that are responsible for its increasing use. Manufacturers are Eastman Chemical, BASF, Mitsubishi Gas, and Union Carbide. World capacity is estimated at 2000 – 2500 t/a.

Physical Properties. Hydroxypivalic acid neopentyl glycol ester is a colorless crystalline solid with a melting point of 50 °C (see Table 1). It is highly soluble in polar organic solvents; its solubility in water is limited to 27.4 % at 25 °C; conversely, 52.4 % water dissolves in HPN.

Chemical Properties. Pure HPN can be distilled at reduced pressure without decomposition up to about 200 °C. In the presence of alkali metal salt impurities, significant decomposition occurs even at temperatures of about 150 °C. Both hydroxyl groups undergo the usual reactions of primary alcohols. As with neopentyl glycol, the quaternary structure contributes to the excellent stability of HPN derivatives.

Production. Hydroxypivalic acid neopentyl glycol ester is produced by a Tishchenko reaction directly from hydroxypivaldehyde in the presence of a basic catalyst (e.g., aluminum oxide) [12] or classically by thermal treatment [13] (Section 2.2.1). Alternatively, it can be synthesized by esterification of neopentyl glycol with hydroxypivalic acid [14]. High-purity hydroxypivalic acid neopentyl glycol ester is obtained by subsequent distillation [15].

Uses. Hydroxypivalic acid neopentyl glycol ester is a diol modification agent in polyesters, polyurethanes, and plasticizers. As a component of polyester varnish systems, HPN has special

advantages with respect to flow properties, adhesion firmness, flexibility, thermal stability, resistance to light (UV), and impact strength at low temperature. The ester is used as a diol component of powder varnishes, coil coatings (e.g., internal coating of cans), electrophoresis varnishes, and unsaturated polyester resins; it is used also in radiation-cured varnish resins, binders for water lacquers, plasticizers, and polyurethane foams.

2.2.3. 2-Methyl-2-propyl-1,3-propanediol and 2-Butyl-2-ethyl-1,3-propanediol

2-Methyl-2-propyl-1,3-propanediol [*78-26-2*] and 2-butyl-2-ethyl-1,3-propanediol [*115-84-4*] (see Table 1) are produced either by the salt-free procedure based on aldol addition followed by hydrogenation [16] or by the classical combination of hydroxymethylation and Cannizarro-type disproportionation with formaldehyde [17] (see Scheme 1).

The production costs are considerably higher than for neopentyl glycol, since the synthesis of 2-methylpentanal and of 2-ethylhexanal from propanal and butanal requires two more steps: aldol condensation and hydrogenation.

Since ca. 1980 2-butyl-2-ethyl-1,3-propanediol has become a very useful diol for polyester or polyurethane coatings [18]. The world production of 2-butyl-2-ethyl-1,3-propanediol is estimated at about 10 000 t/a; the main producer is Neste.

The best known fine chemicals produced from 2-methyl-2-propyl-1,3-propanediol are the dicarbamates Meprobamate (β-methyl-β-propyltrimethylene dicarbamate [*57-53-4*]), used as a tranquilizer, and Carisoprodol (*N*-isopropyl-β-methyl-β-propyl-trimethylene dicarbamate [*78-44-4*]), used as a muscle relaxant.

2.2.4. 2-*sec*-Butyl-2-methyl-1,3-propanediol

2-*sec*-Butyl-2-methyl-1,3-propanediol (see Table 1) [*813-60-5*] can be made via 2,3-dimethylbutanal by simultaneous aldol addition and Cannizzaro reaction with formaldehyde [25]. So far it has been used only in the production of the tranquilizer Mebutamate (β-*sec*-butyl-β-methyl-trimethylene dicarbamate [*64-55-1*]).

2.2.5. 1,3-Propanediol

1,3-Propanediol [*504-63-2*] is a colorless liquid at room temperature in contrast to 2,2-dialkyl-1,3-diols (see Table 1). 1,3-Propanediol is produced commercially by Degussa starting from acrolein [*107-02-8*].

$$CH_2CHCHO + H_2O \longrightarrow HOHCH_2CH_2CHO$$

$$HOHCH_2CH_2CHO + H_2 \longrightarrow HOHCH_2CH_2CH_2OH$$

The addition of water under mild acidic conditions gives 3-hydroxypropionaldehyde [*2134-29-4*] with high selectivity (see Scheme 1). Preferentially buffer solutions with a pH 4 – 5 [19] or weak acidic ion exchange resins [20] are used as catalysts. Further hydrogenation of this aqueous solutions gives 1,3-propanediol [21]. There is an alternative route via hydroformylation of ethylene oxide and subsequent hydrogenation of the intermediate 3-hydroxypropionaldehyde [22].

A new large market for 1,3-propanediol will be in polyester coatings and in the production of poly(trimethylene terephthalate), a new material for the production of high quality carpet fibers [23].

2.2.6. 2-Methyl-1,3-propanediol

2-Methyl-1,3-propanediol [*2163-42-0*] is a fairly new commercially available diol and is produced by Arco with an estimated capacity of about 7000 t/a [24]. The process is designed for the production of 1,4-butanediol [*110-63-4*] as an alternative to Reppe technology and the acetoxylation of butadiene.

The raw material propylene oxide [*75-56-9*] is isomerized to allyl alcohol [*107-18-6*] in the first step. Hydroformylation of allyl alcohol gives 4-hydroxybutanal (79 %) [*25714-71-0*] and 3-hydroxy-2-methylpropanal (11 %) [*38433-80-6*]. The last step comprises hydrogenation of the *n* and *iso* intermediates to the corresponding diols. 2-Methyl-1,3-propanediol is used in polyester coatings.

2.3. 1,6-Hexanediol

1,6-Hexanediol [*629-11-8*], hexamethylene glycol, $HOCH_2(CH_2)_4CH_2OH$, colorless crystals (see Table 1), is soluble in water and other polar solvents.

Production. 1,6-Hexanediol is produced industrially by the catalytic hydrogenation of adipic acid or of its esters. Mixtures of dicarboxylic acids and hydroxycarboxylic acids with C_6 components formed in other processes (e.g., in cyclohexane oxidation) also can be used.

The acids are hydrogenated continuously at 170–240 °C and at 15.0–30.0 MPa (150–300 bar) on a suitable catalyst either in a trickle-flow (downflow) or a bubble-flow (upflow) fixed-bed reactor. The reactor temperature is controlled by circulating part of the reactor discharge. The hydrogen required for the hydrogenation is fed together with the recycle gas through the recycle gas compressor to the reactor (see Fig. 1).

Figure 1. Hydrogenation of adipic acid or of its esters (trickle-flow fixed bed)

Side products of the synthesis are alcohols, ethers, diols, and esters. Pure 1,6-hexanediol is obtained by fractional distillation of the crude reactor discharge.

For the hydrogenation of dicarboxylic acids, catalysts containing cobalt, copper, or manganese are suitable [26]. For the hydrogenation of esters, catalysts such as copper chromite or copper with added zinc and barium are used as "full catalysts" or on inert carriers [27], [28]. Both acids and esters also may be hydrogenated using suspended catalysts.

Quality and Analysis. The assay of the pure product is about 98 %; impurities are various diols and ε-caprolactone as well as traces of water. The color number of the product determined photometrically according to the Pt/Co scale must not exceed 15 APHA. Above 70 °C, 1,6-hexanediol tends to turn yellow.

Storage and Transportation. 1,6-Hexanediol in the form of flakes or as a solidified melt is stored and shipped in barrels. It is transported as a melt in stainless steel containers, tank trucks, or tank cars.

Uses and Capacity. The most important use of 1,6-hexanediol is in the synthesis of polyesters and polyurethanes. In addition it is used in the production of varnishes, adhesives, pharmaceuticals, and textile auxiliaries.

The world capacity of 1,6-hexanediol is ca. 25 000 t/a; manufacturers are BASF and Ube.

2.4. Hexynediols

2.4.1. 3-Hexyne-2,5-diol

3-Hexyne-2,5-diol [*3031-66-1*] is a more or less solid yellow mass of crystals (see Table 1) depending on the relative content of the *meso* form. It is miscible with water and polar solvents.

$CH_3CH(OH)\text{-}C{\equiv}C\text{-}CH(OH)CH_3$

3-Hexyne-2,5-diol is produced by BASF from acetylene and acetaldehyde by the Reppe ethynylation method (→ Acetylene). 3-Hexyne-2,5-diol is used, for example, as a brightener for nickel baths (80 % aqueous solution) or as starting material for production of 2,5-hexanediol [28], but especially in the production of 4-hydroxy-2,5-dimethyl-3-(2*H*)-furanone [*3658-77-3*], trade name Furaneol [29], used as pineapple and strawberry flavor.

2.4.2. 2,5-Dimethyl-3-hexyne-2,5-diol

2,5-Dimethyl-3-hexyne-2,5-diol [*142-30-3*], $(CH_3)_2C(OH)\text{-}C{\equiv}C\text{-}C(OH)(CH_3)_2$, white crystals (see Table 1), is produced by addition of acetone to acetylene. It is an intermediate of minor importance in the production of 2,5-bis(*tert*-butylperoxy)-2,5-dimethyl-3-hexyne, which is used as an initiator in polymerization processes, as well as in the production of moschus fragrances, of chrysanthemumic acid, and of surfactants (surfinols) by oxalkylation (Air Products). Manufacturers are Enichim and Air Products.

2.5. 1,10-Decanediol

1,10-Decanediol [*112-47-0*] (see Table 1) is produced from sebacic acid by a process analogous to that described for 1,6-hexanediol [30] (see Section 2.3). It is an intermediate of minor importance in the production of polyesters and polyurethanes.

$HOCH_2(CH_2)_8CH_2OH$

Manufacturers are Ashland and Degussa-Hüls.

2.6. 2,2-Bis(4-hydroxycyclohexyl) propane

2,2-Bis(4-hydroxycyclohexyl)propane [*80-04-6*] is a crystalline, colorless, and odorless compound (see Table 1).

The conformation of the cyclohexane rings gives rise to *cis-cis*, *cis-trans* and *trans-trans* isomers. The industrial product is a mixture of these stereoisomers. The physical properties depend on the relative amounts of the isomers present. The *trans-trans* compound has the lowest energy and is formed from the other isomers at higher temperature. It has the lowest solubility in solvents such as methanol, butanol, and acetone and has the highest melting point of these isomers.

Production. 2,2-Bis(4-hydroxycyclohexyl)propane is produced by hydrogenation of bisphenol A, 2,2-bis(4-hydroxyphenyl)propane [*80-05-7*], an industrially important compound made from acetone and phenol (→ Phenol Derivatives). Bisphenol A is hydrogenated at about 25.0 MPa (250 bar) and at 200 °C on a nickel, cobalt, or ruthenium catalyst [31–33].

Uses. 2,2-Bis(4-hydroxycyclohexyl)propane is used mainly in synthetic materials as a bifunctional component, e.g., as a modifier in the production of saturated and unsaturated polyester resins, and of oil- and fatty-acid-containing alkyd resins. Exchange of hydroxyl for amino gives a diamine which can be used in the production of glass-clear polyamides.

2.7. 1,4-Bis(hydroxymethyl)cyclohexane

1,4-Bis(hydroxymethyl)cyclohexane [*105-08-8*] is commonly known as 1,4-cyclohexanedimethanol (CHDM), also as 1,4-dimethylolcyclohexane, or hexahydro-*p*-xylylene glycol.

The compound became known in the 1960s mainly for its use in polyester films and fibers highly resistant to hydrolysis.

Physical Properties (see also Table 1). 1,4-Cyclohexanedimethanol is colorless and has a slight odor. The softening point of the *cis* isomer is 43 °C, that of the *trans* isomer 67 °C. *Cis – trans* mixtures can be isomerized at 200 °C in the presence of alkoxides to an equilibrium mixture of 42 % *cis* and 76 % *trans*. The commercial product consists of a mixture of *cis* and *trans* isomers with a typical ratio of 1/3.

1,4-Cyclohexanedimethanol is miscible with water as well as with low molecular mass alcohols; it is very slightly soluble in hydrocarbons and ethers. Its solubility at 20 °C (g in 100 g solvent) in benzene is 1.1, in trichloromethane 5.7, in water 92.0, and in methanol 92.2.

Chemical Properties. CHDM undergoes the characteristic reactions of a diol with two primary hydroxyl functions. In contrast to 1,2- and 1,3-diols reactions of CHDM with aldehydes or ketones do not result in the formation of heterocyclic products, such as 1,3-dioxolanes or 1,3-dioxenanes.

Production. The commercially important process for producing CHDM is the hydrogenation of dimethyl terephthalate (DMT) [*120-61-6*]via dimethyl hexahydroterephthalate (DMHT) [*94-60-0*] in a methanolic solution or in the molten state [34]:

The hydrogenation plant consists of two reactors. In the first reactor, a continuous circulation of product DMHT and of DMT is maintained. The molten DMT is pumped into the inlet of this reactor, which operates at 30 – 48 MPa and 160 – 180 °C with a commercial supported Pd catalyst. Temperature control is achieved by operating at sufficiently high cross-sectional loadings of the mixture of ca. 10 % in product DMHT. This allows the radial dissipation of heat via the reactor walls and largely avoids high temperature peaks. The cooled reactor effluent, which contains only minor amounts of unreacted DMT, is divided: 8 – 10 parts are recycled via a pump and heat exchanger to the reactor inlet. The remaining 1 – 2 parts (the exact amount corresponds to the amount of fresh DMT) are fed continuously into the second reactor for the final Pd-catalyzed hydrogenation.

An advantage of this process is that DMT can be hydrogenated as ca. 10 % dilute feed without handling large amounts of liquid. The yield of DMHT is typically 97 – 98 %, with methyl 4-methyl-4-cyclohexanecarboxylic acid methyl ester [*51181-40-9*] and some 1-hydroxymethyl-4-methylcyclohexane [*34885-03-5*] as main byproducts.

1,4-Bis(hydroxymethyl)cyclohexane (CHDM) is formed in the second stage of the hydrogenation. The crude DMHT of stage one is used in a plant analogous to that of the first stage [40], although any conventional hydrogenation plant can be used since the heat of the ester hydrogenation is comparatively small.

The industrial processes use commercial copper chromite catalysts. The effects of catalyst, residence time, and temperature must be carefully adjusted in order to achieve a *cis*/*trans* ratio of 1/3 to 1/4 in the CHDM product.

A constant isomer ratio is important for further processing of CHDM in polyester formation since the crystal structures of polyesters of *cis*- and *trans*-CHDM differ and thus influence the melting range and density of polyester fibers.

In addition to the side products of the first hydrogenation stage, 4-methyloxymethylhydroxymethylcyclohexane and bis(4-hydroxymethylcyclohexyl) ether can be formed in the second stage of ester hydrogenation. The Eastman process (see above) [34] avoids the formation of high-boiling compounds and thus saves cumbersome separation of side products by fractionation in vacuum. The diol is purified by simply removing methanol and low-boiling compounds. The CHDM of fiber quality obtained by this method is ca. 99 % pure.

Pure CHDM may also be obtained by recycling waste poly(1,4-cyclohexylene dimethylene terephthalate) by first cleaving the polyester in the presence of low molecular mass alcohols and then subjecting the resulting mixture to a hydrogenation analogous to that described above [35]. Estimated world capacity is 55 000 t/a.

Uses. An important application of CHDM is still the production of terephthalate – polyester fibers with lower densities and higher melting points than analogous fibers using ethylene glycol. They are more stable to hydrolysis and have more favorable electrical properties than similar polyesters made from other diols [35].

Unsaturated resins based on CHDM are characterized by very good properties with respect to water absorption, thermal stability, and resistance to environmental and chemical exposure [36]. The use of CHDM in saturated polyester resins leads to powder, waterborne, and solvent-based coatings with excellent hardness and durability [37]. 1,4-Cyclohexanedimethanol is of increasing interest for application in polyurethanes and poly-

carbonates [38] as well as an antifogging agent and as a sensitizing additive in silver bromide emulsions.

2.8. 2,2,4-Trimethyl-1,3-pentanediol

2,24-Trimethyl-1,3-pentanediol [*144-19-4*], TMPD glycol, is a white crystalline solid (see Table 1). It is a versatile diol with a wide range of applications including polyester resins, polyurethane foams, and lubricants.

Physical and Chemical Properties. TMPD glycol is only slightly soluble (< 2 %) in water and kerosene, but very soluble (up to 80 %) in alcohols. The solubility in benzene, acetone, and ethers is at most 29 %.

TMPD glycol, with one primary and one secondary hydroxyl function, shows the typical reactivity of a diol. In comparison to other diols, such as CHDM (see Section 2.7) or NPG (see Section 2.2.1), TMPD glycol has an unsymmetrical structure and shielded hydroxyl groups.

Production. TMPD glycol is produced by homo-aldol condensation of isobutyraldehyde [*78-84-2*] in the presence of an alkaline catalyst followed by hydrogenation of the resulting cyclic acetal to give TMPD glycol and isobutanol. Eastman Chemical is the only manufacturer of TMPD glycol.

Uses. TMPD glycol is mainly used as raw material in the production of unsaturated and saturated polyesters (e.g. for waterborne or high-solids coatings) and as an intermediate for polyesters used in the manufacture of polyurethane elastomers and foams [39]. These resins are very stable to hydrolysis and resistant to corrosion, as well as having other desirable features, such as low density, low viscosity, and good compatibility.

2.9. Vicinal Diols by Hydroxylation of Olefins with Peracids

Some vicinal diols are manufactured on a commercial scale by the reaction of an alkene with an organic peracid, such as performic acid, produced in situ, or peracetic acid [41]. An epoxide is formed initially; acid-catalyzed cleavage of the epoxide ring leads to a 1,2-diol or a 2-hydroxyalkyl-ester or a mixture of the two. The 2-hydroxyalkyl ester is hydrolyzed to the 1,2-diol by the subsequent treatment with a base.

2.9.1. 1,2-Pentanediol

1,2-Pentanediol [*5343-92-0*], 1,2-dihydroxypentane, $CH_3(CH_2)_2CH(OH)CH_2OH$, is a colorless and odorless liquid which is miscible with water and polar organic solvents (see also Table 1).

The compound is made by treating a mixture of 1-pentene and formic acid with 40 % hydrogen peroxide at 30 °C [42]. 1,2-Pentanediol has attained commercial importance as a synthetic building block for systemic fungicides [43] and as a moisturizing agent in cosmetics.

2.9.2. Other 1,2-Diols

Pinacol [*76-09-5*], 2,3-dimethyl-2,3-butanediol, $(CH_3)_2C(OH)C(OH)(CH_3)_2$, colorless crystals, is soluble in hot water, alcohol, and ether and slightly soluble in cold water and carbon disulfide. The hexahydrate, *mp* 45 °C, crystallizes as four-sided plates (see also Table 1).

1,2-Hexanediol [*6920-22-5*], (*bp* 108 °C/0.5 hPa; ϱ 0.953 g/cm^3 at 20 °C) is a colorless liquid miscible with water. It is used in printing inks and in cosmetics.

1,2-Octanediol [*1117-86-8*] (*bp* 140 °C/1.6 hPa) is a white waxy solid, slightly soluble in water. Its production is described in [42], [44]. It is used in printing inks and in cosmetics.

3. Triols

3.1. Trimethylolpropane

Properties. Trimethylolpropane [*77-99-6*], 2-ethyl-2-hydroxymethyl-1,3-propanediol, $CH_3CH_2C(CH_2OH)_3$, is a colorless, crystalline, trivalent alcohol (see Table 1). Trimethylolpropane is quite soluble in water and polar organic solvents. The three primary hydroxyl groups undergo the normal OH group reactions.

Production. Trimethylolpropane is made by the base-catalyzed aldol addition of butyraldehyde with formaldehyde followed by Cannizzaro reaction of the intermediate 2,2-bis(hydroxymethyl)butanal with additional formaldehyde and at least a stoichiometric quantity of base (see Scheme 1):

Sodium hydroxide [45], [46] or calcium hydroxide [47], [48] are used as bases in industrial-scale production. The yield in both cases is ca. 90 %. Many attempts have been made to avoid the large quantities of formate byproduct by catalytic hydrogenation of the 2,2-bis(hydroxymethyl)butanal [49], [50]. These processes have been achieved by using tertiary amines as catalyst and transforming the formed ammonium formate into methyl formate [87] or even avoiding the formation of larger amounts of formates [88].

Various procedures have been suggested for separating the trimethylolpropane from the formate. For instance, the concentrated reaction solution can be extracted with an organic solvent, which is then evaporated and the crude trimethylolpropane is purified by vacuum distillation [51], [52], [53]. In another variant [54], the aqueous reaction solution is evaporated until most of the sodium formate crystallizes and is removed by hot filtration. The liquid trimethylolpropane which remains is liberated of residual salts with an ion exchanger and then distilled. The removal of discoloring impurities is described in [55].

Cyclic diethers of the acetal type (1,3-dioxanes, formals) can be converted into TMP and methanol by metal-catalyzed hydrogenation [56].

Uses. Large quantities of trimethylolpropane and its ethoxylated derivatives are used as precursors for urethanes and polyester resins. Another important field of application is in medium-oil and short-oil alkyd resins (→ Alkyd Resins). The resulting lacquers are characterized by excellent resistance to alkali, detergents, and water, combined with outstanding impact resistance and flexibility, as well as excellent clearness and clearness retention.

Reaction products with fatty acids ($C_5 - C_{10}$) are components of synthetic lubricants. A strongly growing market will be the use of these blended polyol esters in chlorine-free, purely fluorocarbon based refrigerant systems. Powder and high-solids coatings represent a strong potential market for TMP, because it contributes to low viscosity. TMP acrylates are used as reactive diluents in UV-cured systems for inks and coatings, and TMP allyl ethers in unsaturated polyesters.

Economic Aspects. World production capacity for trimethylolpropane was estimated at 150 000 t in 1998, of which about 67 000 t was accounted for by Western Europe, 60 000 t by the United States, and 15 000 t by Japan. The main producers are Bayer, Perstorp, and Polioli in Western Europe; Celanese and Perstorp in the United States; and Koei and Mitsubishi Gas in Japan.

3.2. Trimethylolethane

Properties. Trimethylolethane [*77-85-0*], 2-hydroxymethyl-2-methyl-1,3-propanediol, $CH_3C(CH_2OH)_3$, is a colorless, crystalline substance (see Table 1), soluble in water (140 g per 100 g at 25 °C), alcohols, and acetone.

Production. Trimethylolethane is made by aldol condensation of propionaldehyde with formaldehyde, followed by reaction of the intermediate 2,2-bis(hydroxymethyl)propanal with

excess formaldehyde in the presence of sodium hydroxide or lime as basic component (see Scheme 1).

$$H_3CCH_2CHO + 3\,H_2CO + NaOH \longrightarrow H_3CC(CH_2OH)_3 + HCOONa$$

The resulting aqueous solution is freed from excess formaldehyde by distillation under pressure and further concentrated. The formate byproduct can be separated by extracting the trimethylolethane from the residue with organic solvents such as 2-propanol [57] or by almost complete removal of the water and dissolving the trimethylolethane in acetone or methanol.

Uses and Economic Aspects. Trimethylolethane, like trimethylolpropane, is a polyol component of short- and medium-oil alkyd resins, in which it results in a shorter drying time and, because of its shorter alkyl chain, a harder lacquer film compared with trimethylolpropane. However, its economic importance is small compared with that of pentaerythritol or trimethylolpropane. It is produced by Mallinckrodt (USA) and Mitsubishi Gas (Japan) in amounts of several thousand tonnes per annum.

4. Tetrols

4.1. Ditrimethylolpropane

Ditrimethylolpropane [*23235-61-2*] 2,2-[oxybis(methylene)]-bis(2-ethyl)-1,3-propanediol is a colorless and crystalline substance (*mp* 112 – 114 °C), only slightly soluble in water at ambient temperature (2.6 g/100 g at 25 °C).

It is a byproduct of TMP production and can be isolated from the residue of the TMP distillation step. Newer investigations show that ditrimethylolpropane can be prepared in high yield and selectivity by the reaction of TMP, formaldehyde, and 2-ethylacrolein [58]. It is used in water-thinnable alkyd resins and as a polyol component in PVC stabilizers based on Ca/Zn alkyl carboxylates. Producers are Perstorp (Sweden) and Mitsubishi Gas (Japan).

4.2. Pentaerythritol

Pentaerythritol [*115-77-5*], 2,2-bis(hydroxymethyl)-1,3-propanediol, $C(CH_2OH)_4$, was discovered by Tollens in 1882 when an aqueous solution of formaldehyde containing some acetaldehyde was allowed to stand with barium hydroxide [59].

Properties. Pentaerythritol is a colorless, crystalline alcohol with four primary hydroxyl groups. It crystallizes in a tetragonal system with. The tetragonal crystals convert into the cubic form at 180 – 190 °C. The compound sublimes on heating in vacuum without dissociation. Important physical data are listed below (see also Table 1):

Heat of combustion (p = const.)	2767 kJ/mol
Heat of formation	931 kJ/mol
Specific heat capacity at 100 °C	255 J/mol
Ignition temperature	390 °C
Solubility in water (per 100 g water)	
at 25 °C	7 g
at 97 °C	77 g

Mixtures of air and pentaerythritol dust are explosive at 490 °C and at dust concentrations of more than 30 g/m^3. The four primary hydroxyl groups undergo the normal reactions of OH groups [60]. Pentaerythritol is oxidized to tris(hydroxymethyl)acetic acid by air in the presence of platinum or palladium [61].

Production. Pentaerythritol is prepared by the reaction of acetaldehyde with formaldehyde in alkaline medium. The aldol addition results in replacement of the three α-hydrogen atoms, leading to trimethylolacetaldehyde (pentaerythrose), which is reduced to pentaerythritol by excess formaldehyde in the presence of base (sodium hydroxide or calcium hydroxide). The yield is approximately 90 %. Catalytic hydrogenation of pentaerythrose, which would avoid the formate byproduct, is not practicable. Higher homologues of pentaerythritol with the general formula

are byproducts of the production of pentaery-

thritol. The product with $n = 2$, known as dipentaerythritol, is the primary contaminant. To minimize its formation it is necessary to increase the ratio of formaldehyde to acetaldehyde beyond the stoichiometric ratio of 4:1 [60]. Additionally, certain amounts of formaldehyde acetals are formed [62]. Both batch and continuous processes for the production of pentaerythritol have been described [63], [64].

To isolate the product, the aqueous reaction solution is first freed of excess formaldehyde and most of the water by distillation under pressure. After further concentration, usually in vacuo, the crude pentaerythritol crystallizes. The mother liquor contains the sodium formate plus residual pentaerythritol. Separation of the formate, recycling of the residual pentaerythritol, and elimination of the wastewater occur in subsequent process steps. The crude pentaerythritol is purified by recrystallization from water after treatment with activated carbon. By using lime, the process runs reversely; first calcium formate separates because of its low water solubility, the mother liquor than contains the dissolved pentaerythrithol. Residual Ca^{2+} or Na^{+} ions can be removed by ion-exchange resins. The wastewater contains a certain amount of dissolved pentaerythritol, which can be recovered [65].

Quality and Analysis. Pentaerythritol is available in various grades which differ in their content of the above-mentioned byproducts including residual ash (alkali metal salts and/or alkaline earth metal salts). Higher ash content often has a detrimental effect on the color of the alkyd resin obtained from the product. Products termed pentaerythritol monograde generally contain more than 97 % pentaerythritol, whereas the technical grade consists of 80 – 95 % pentaerythritol and 5 – 15 % dipentaerythritol.

For *quality control*, the melting point, hydroxyl number, ash content, and the color or iodine number of the melt are determined. Gas chromatographic analysis after silylation with agents such as *N*-methyl-*N*-trimethylsilyltrifluoracetamide [66] gives precise information on the composition of the sample. Analysis by high-pressure liquid chromatography has also been described [67].

Uses. The major application of pentaerythritol (ca. 70 %) is the production of long-oil and medium-oil alkyd resins. The pentaerythritol structure gives the resin outstanding properties both in processing and end use. Resins prepared from pentaerythritol and rosin or tall oil are used for the modification of printing inks and nitrocellulose lacquers and for the preparation of adhesives and core binders. Solvent-free, water-thinnable alkyd resin emulsions can be prepared by using tribasic acids in the esterification process, which gives water-dispersible salts after neutralization.

Pentaerythritol esters of short- to medium-chain carboxylic acids ($C_5 - C_{10}$) are applied as high-temperature synthetic lubricants, lubricant additives, and plasticizers. An emerging market for these esters is as refrigerant lubricants. Because of the ozone-depleting properties of CFCs they are to be replaced by chlorine-free fluorocarbons. However, since this class of compounds differs in polarity the compressor must be lubricated with oils of higher polarity [68], [69] Pentaerythritol tetranitrate is used as a detonator in fuses and, to a limited extent, as a military explosive. The tetranitrate also is used in medicine as a long-term coronary vasodilator.

Finely ground pentaerythritol in combination with metal soaps serves as a nontoxic costabilizer for poly(vinyl chloride). It also is used in flame retardant compositions (intumescent paints). Under the action of heat an insulating foam layer forms, up to 50 times the thickness of the original coating. Pentaerythritol triacrylate is used as an active diluent in radiation-cured paints. Pentaerythritol adducts with ethylene oxide are used as emulsifiers, inorganic phosphoric or phosphoric esters are used as additives in hydraulic fluids, and tetraesters with sterically hindered phenylcarboxylic acids act as a highly effective antioxidant in plastics.

Economic Aspects. In 1998, world production capacity was estimated to be 360 000 t, 71 000 t of which was in the United States, 120 000 t in Europe, 27 000 t in Japan, and 25 000 t in Canada. Smaller producers are located in many other countries. The main manufacturers are Perstorp, Hoechst-Celanese, and Degussa-Hüls. The overall pentaerythritol market is expected to grow at a rate of 1.5 – 2 %/a. The alkyd resin market should be stable, and growing use of fatty acid esters in refrigerant systems can be assumed.

5. Higher Polyols

5.1. Dipentaerythritol

Dipentaerythritol [*126-58-9*], 2,2-[oxybis(methylene)-bis[2-hydroxymethyl]-1,3-propanediol, is a byproduct of pentaerythritol production. Because of its low solubility in water (0.22 g/100 g H_2O at 20 °C and 10.0 g/100 g H_2O at 100 °C) it can be separated from pentaerythritol by fractional crystallization. The yield can be increased by changing the ratio of formaldehyde/acetaldehyde towards stoichiometric. Adding pentaerythritol before starting the reaction also increases the yield. An effective method is to use acrolein instead of acetaldehyde [70], [71].

In the last decade the consumption of dipentaerythritol steadily increased. The main outlets are $C_5 - C_{10}$ ester lubricants for jet engines and refrigerator systems [72], dipentahexaacrylate as cross-linking agent for UV-curing acrylates, for water-resistant intumescent paints, alkyd resins with low viscosity (high solids), and as a nonsubliming polyol component in nontoxic PVC stabilizer systems.

The total installed capacity is ca. 6000 t. Main producers are Hercules, Koei, Perstorp, Polialco, and Degussa-Hüls.

5.2. Tripentaerythritol

Tripentaerythritol [*78-24-0*], 2,2-bis[hydroxy-2,2-bis(hydroxymethyl)propoxy]methyl-1,3-propanediol is only slightly soluble in cold and hot water and can be isolated during the production of dipentaerythritol. It has at present only a very limited economic importance.

6. Toxicology

Table 2 summarizes the acute toxicity data of polyhydric alcohols. According to the lethal doses shown, these compounds are generally little toxic. For comparison, the LD_{50} values of the butanediols also are included in Table 2.

TMPD Glycol, 2,2,4-trimethyl-1,3-pentanediol, is classified as "slightly toxic" [78], [79], see Table 2. In rabbits, moderate eye irritation was observed. Slight to no skin irritation occurred in guinea pigs, and no skin sensitization was found. Repeated skin application studies in humans gave no evidence of irritation, sensitization, photosensitization, or systemic toxic effects. In humans, TMPD glycol is rapidly excreted in the urine, partly unchanged, partly as the glucuronide and sulfate conjugates, and partly as 2,2,4-trimethyl-3-hydroxyvaleric acid.

1,4-Bis(hydroxymethyl)cyclohexane (CHDM) has a low acute toxicity (see Table 2). For metabolism of CHDM in rats, see [80].

Trimethylolpropane is practically nontoxic (see Table 2). Skin irritation was not observed.

Pentaerythritol is practically nontoxic. Health disturbances resulting from handling pentaerythritol have never been observed. High oral doses (50 g) administered to humans resulted only in slightly increased pulse rate [85]. Diarrhea was observed at high doses in animals. Pentaerythritol is readily biodegradable under aerobic conditions according to OECD Guideline No. 301 [86].

1,2-Diols. The oral LD_{50} values in rats for 1,2-hexane-diol, 1,2-octanediol, are included in Table 2. For these 1,2-diols, skin irritation was not observed in rabbits. 1,2-Octanediol caused no eye irritation in rabbits; testing in guinea pigs resulted in a slight sensitization reaction.

1. Introduction

Aldehydes are represented by the general formula RCHO, where R can be hydrogen or an aliphatic, aromatic, or heterocyclic group.

According to IUPAC nomenclature, aldehydes are identified by the ending "al." However, many of them still are called by their common names.

Because of their high reactivity, aliphatic aldehydes are widely used as intermediates in organic synthesis. Sometimes the isolation of a pure aldehyde is very difficult; in such cases, stable derivatives or oligomers are prepared from which the aldehydes can be reisolated.

Aldehydes usually must be kept from contact with air and under certain circumstances must be stabilized during distillation, subsequent storage, and transportation. This applies particularly to unsaturated aldehydes, which have a tendency to polymerize (e.g., on contact with alkali). For commerical purposes aldehydes often are protected by the addition of stabilizers and antioxidants and by a nitrogen atmosphere. When handling aldehydes, care must be taken to prevent either the liquids or their vapors from coming into contact with respiratory organs, eyes, and skin. Gloves and safety glasses are absolutely necessary.

Aldehydes are obtained mainly via the oxo synthesis, by mild oxidation (dehydrogenation) of primary alcohols, and by special olefin oxidation processes. Low concentrations of aldehydes occur naturally in essential oils of various plants. Acetaldehyde is an intermediate product of alcohol fermentation; it is formed by decarboxylation of the intermediate pyruvic acid. Aldehydes also fulfill some important biological functions, e.g., 11-*cis*-retinal in the sight process or as pyridoxal in the transamination of amino acids. Their isolation from natural substances is of commercial significance only in a few cases, e.g., in the production of longer-chain fragrance aldehydes.

2. Saturated Aldehydes

The most important saturated aliphatic aldehydes are formaldehyde, acetaldehyde, propionaldehyde, and butyraldehydes; they are used as starting materials for organic chemicals and polymers (→ Formaldehyde, etc.). Some dialdehydes, e.g., glyoxal, are also commerical products (→ Glyoxal). The higher aliphatic aldehydes are used mostly for the production of alcohols, carboxylic acids, amines, etc. The aldehydes also serve as fragrances in the perfume industry.

2.1. Physical Properties (see Table 1)

Formaldehyde, the simplest saturated aliphatic aldehyde, is a gas at room temperature. The aldehydes up to about C_{12} are liquids; the straight-chain aldehydes from C_{13} and above are solids. Because the hydrogen atom of a formyl group has less tendency to hydrogen bond than the hydrogen atom of a hydroxy group, the boiling points of the aldehydes are considerably lower than those of the corresponding alcohols. The difference in boiling points between aldehydes and alcohols with an intermediate number of carbon atoms is 20 – 40 °C.

Viscosity, density, and refractive index at 20 °C increase with increasing molecular mass. The lower homologues are mobile liquids; aldehydes from heptanal to undecanal have an oily consistency.

There are practically no limits to the miscibility of formaldehyde and acetaldehyde with water. However, with increasing molecular mass the solubility of aldehydes decreases very rapidly. For example, the solubility of hexanal in water is only 0.6 wt % at 20 °C. The aliphatic aldehydes are soluble in alcohols, ethers, and other common organic solvents.

Whereas the lower aldehydes have a pungent smell, the higher homologues in the $C_8 - C_{13}$ range are components of nearly all perfumes and many fragrances. Their odors become weaker with increasing molecular mass.

The characteristic properties of most aliphatic aldehydes are their ease of autoxidation and their tendency to trimerize and/or polymerize. Therefore, aldehydes are protected with an

[b] effective density at −19 °C

inert gas atmosphere and minimal amounts of a stabilizer are added if required [1, p. 651].

Because of the differences in boiling points between aldehydes and alcohols, aldehydes prepared by dehydrogenation of the corresponding alcohols generally are separated and purified by distillation. Apart from the lower boiling, short-chain aldehydes, distillation is mostly carried out at reduced pressure [1, p. 654]. Numerous aldehydes form azeotropic mixtures with water (see Table 2) and other substances.

Table 2. Azeotropic mixtures of aldehydes with water [9]

Aldehyde	*bp* of aldehyde, °C	*bp* of azeotrope, °C	wt% H_2O in azeotrope
Propanal	47.9	47.5	2.0
Butanal	74.8	68.0	9.7
2-Methylpropanal	63.3	60.1	9.6
Pentanal	103.3	83.0	19.0
3-Methylbutanal	92.5	77.0	12.0
Hexanal	128.3	91.0	31.3
2-Ethylbutanal	116.7	87.5	23.7
2-Methylpentanal	118.3	88.5	23.0
2-Ethylhexanal	163.6	96.4	51.6

2.2. Chemical Properties

The polarity of the carbonyl group of aldehydes not only facilitates the typical aldehyde reactions – addition of nucleophiles, reduction, and oxidation – but it also makes the α-hydrogen atom acidic. For these reasons, aldehydes can undergo a wide variety of reactions. The major ones are compiled in Table 3 [1, p. 609].

Addition Reactions. Because of the polarity of the carbonyl double bond, aldehydes enter into a wide variety of nucleophilic addition reactions. The simplest case is the intermolecular addition of one molecule of aldehyde to another to form an aldol. These *aldols* (β-hydroxyaldehydes) generally are unstable and react further to form secondary products, i.e., diols, unsaturated aldehydes, or alcohols.

Industrially, crossed aldol condensation of an aldehyde with formaldehyde is used for the production of trimethylolpropane, pentaerythritol, and neopentyl glycol (→ Alcohols, Polyhydric). The aldol condensation of butanal for the production of the plasticizer alcohol 2-ethylhexanol is of major commercial importance (→ 2-Ethylhexanol).

Table 3. General reactions of aliphatic aldehydes

The addition of alcohols and thiols to aldehydes leads to acetals and monothiohemiacetals; these are used for the protection of formyl groups in synthesis because they are resistant to alkali. Reductive amination of aldehydes with ammonia or primary amines in the presence of hydrogen or some other reducing agent gives primary or secondary amines, respectively, e.g.,

The reaction with secondary amines yields the corresponding enamines, which can be hydrogenated to tertiary amines.

Classically, aldehydes were identified by the preparation of crystalline derivatives, e.g., by reaction with hydrazine, substituted hydrazines (e.g., 2,4-dinitrophenylhydrazine), hydroxylamine, or semicarbazide. However, now other techniques are used (see Chap. 9).

The addition of Grignard compounds leads to secondary alcohols. The Darzens condensation of alkyl chloroacetates in the presence of a strong base yields aldehydes containing one additional methylene group, e.g.,

With the alkylhaloacetates in the presence of zinc, 3-hydroxycarboxylates are obtained (Reformatsky reaction).

The addition of sodium hydrogensulfite leads to water-soluble crystalline compounds. This reaction permits the separation of α-methyl-branched aldehydes from the isomeric straight-chain aldehydes [10], [11]. The reaction of hydrogen cyanide with aldehydes is of commercial significance. The highly unstable cyanohydrins can be converted to the unsaturated nitriles by dehydration or to the α-hydroxycarboxylic acids by hydrolysis. If the reaction of hydrogen cyanide with aldehydes is carried out in the presence of ammonia, α-amino acids are obtained.

Polymerization. The formation of cyclic, 2,4,6-trialkyl-1,3,5-trioxane type trimers is catalyzed by various acids.

At higher temperature these compounds are unstable and revert to the monomer. With this process pure *n*-alkanals can be isolated from *n*–*iso*-aldehyde mixtures [12].

Mainly oligomers and polymers are formed by the lower aldehydes. Polymeric formaldehyde, referred to as paraformaldehyde, is a mixture of polyoxymethylene glycols $HO(CH_2O)_nH$, where n is 8–100. The oligomers of acetaldehyde, paraldehyde and metaldehyde are 2,4,6-trimethyl-1,3,5-trioxane and the cyclic tetramer, respectively. Polyacetaldehyde is a high-molecular mass polymer with an acetal structure.

Oxidation. A characteristic feature of most aldehydes is their great tendency to autoxidize in a radical chain reaction to the corresponding carboxylic acids. On an industrial scale the oxidation is usually carried out in the liquid phase with oxygen or air. Catalysts often are added to reduce the reaction time and lower the reaction temperature. Salts of transition metals are effective catalysts. For special purposes, hydrogen peroxide, periodic acid, nitric acid, potassium permanganate, chromium trioxide, and peroxo compounds are used as oxidizing agents [1, p. 609]. Another special method is the melting of aldehydes with alkali, e.g., [13].

Hydrogenation (Reduction). Catalytic hydrogenation leads to primary alcohols. Both Ni and Cu catalysts have proved to be the most suitable [14]. Normally, the reaction is carried out in the liquid phase on fixed-bed catalysts at 20–200 °C and pressures of up to 30 MPa (→ Alcohols, Aliphatic, Chap. 2.3.3.). Hydrogenation in the gas phase is run continuously. Because of the good heat dissipation this is advantageous, especially with sensitive starting materials.

In addition to catalytic hydrogenation there are many other reduction processes. Complex hydrides such as lithium aluminum hydride and sodium borohydride are used most frequently as reducing agents.

An important reaction characteristic of aldehydes is the Meerwein–Ponndorf–Verley reduction with aluminum alkoxides, in particular with aluminum triisopropoxide. Because this reaction is reversible the carbonyl compound formed is distilled from the alkoxide. The process is recommended for the preparation of alcohols containing halo or nitro groups.

There are numerous other reducing agents for aldehydes; most of these are of interest only for laboratory syntheses. A few

are: potassium – ammonia, trimethyl phosphite, magnesium, aluminum – mercury, trialkylboranes, and aluminum trialkyls.

The reduction of aldehydes to the corresponding saturated hydrocarbons is of no commercial significance. In laboratory syntheses it is achieved with reducing agents such as hydrazine, complex metal hydrides, lithium – ammonia, or hydrogen iodide – phosphorus.

2.3. Production

Although many aldehyde syntheses are known, only a few are used on an industrial scale. Often this is a question of the availability of feedstock.

The most important processes for the preparation of saturated aliphatic aldehydes are:

1) Hydroformylation of olefins (oxo synthesis)
2) Dehydrogenation or oxidation of primary alcohols (mainly for the production of formaldehyde from methanol)
3) Hydration of acetylene for the production of acetaldehyde (→ Acetaldehyde)
4) Oxidation of ethylene to acetaldehyde (→ Acetaldehyde)
5) Oxidation of saturated hydrocarbons (C_3, C_4) for the preparation of lower aldehydes

In addition, some special syntheses for the production of aldehydes required in the perfume industry are of industrial importance.

Oxo Synthesis. The oxo synthesis is the most important process for the production of aldehydes containing at least three carbon atoms (→ Oxo Synthesis). In this process olefins react with synthesis gas (CO, H_2) to form aldehydes with one more carbon atom than the starting material. Pure products are formed only from symmetrical or sterically hindered olefin molecules; otherwise, product mixtures of straight-chain and branched compounds are obtained:

By the selection of suitable catalysts and reaction conditions the *n* : *iso* ratio can be varied over a wide range.

Dehydrogenation/Oxidation of Primary Alcohols. Dehydrogenation, oxidation, and oxidative dehydrogenation proceed according to the following equations:

$$RCH_2OH \rightarrow RCHO + H_2$$
$$\Delta H = +\,84\,\text{kJ/mol for R} = CH_3 \quad (1)$$
$$RCH_2OH + \tfrac{1}{2}\,O_2 \rightarrow RCHO + H_2O$$
$$\Delta H = -\,159\,\text{kJ/mol for R} = H \quad (2)$$
$$RCH_2OH \rightarrow RCHO + H_2\,, H_2 + \tfrac{1}{2}\,O_2 \rightarrow H_2O$$
$$\Delta H = -\,159\,\text{kJ/mol for R} = H \quad (3)$$

Dehydrogenation. The endothermic dehydrogenation reaction of alcohols is carried out at atmospheric pressure and 250 – 400 °C, normally with Cu or Ag catalysts. The catalysts often are activated by the addition of, e.g., Zr, Co, or Cr. The advantage of this process is the simultaneous recovery of hydrogen that can be used without further purification [2, p. 282]. Catalytic dehydrogenation is an equilibrium reaction. Therefore, high temperatures and short residence times are economically advantageous.

The process still has some commercial importance in the preparation of acetaldehyde from ethanol. The gas-phase dehydrogenation is carried out at atmospheric pressure and 270 – 300 °C on a copper catalyst activated with cerium. Twenty-five to 50 % of the ethanol is converted per throughput, with a selectivity of 90 – 95 % acetaldehyde; ethyl acetate, ethylene, crotonaldehyde, and higher alcohols are obtained as byproducts (for further details → Acetaldehyde).

Oxidation. The oxidation according to Equation (2) is carried out with an excess of air or oxygen at 350 – 450 °C over a catalyst containing 18 – 19 wt % Fe_2O_3 and 81 – 82 wt % MoO_3 [15]. This process is used in the production of formaldehyde (→ Formaldehyde).

Oxidative Dehydrogenation. Equation (3) can be separated formally into the endothermic dehydrogenation of the alcohol and the exothermic combustion of the hydrogen formed; the overall reaction therefore can become exothermic. In the industrial process the two reactions take place simultaneously when substoichiometric quantities of oxygen or air are used. In

oxidation and oxidative dehydrogenation the explosion ranges of the alcohol – air mixtures must be considered.

Oxidative dehydrogenation is the most important process for the production of aldehydes from alcohols. Silver catalysts are preferred but copper catalysts are used also.

In formaldehyde production from methanol, 75 – 99 % conversion is achieved on silver crystals (grain size 0.2 – 3 mm), silver nets, or silver on Al_2O_3. Temperatures of 500 – 720 °C and residence times of less than 0.01 s are used (→ Formaldehyde).

In 1979 about 15 % of Western Europe's acetaldehyde production was from ethanol. Silver and copper were the main catalysts employed. Ethanol conversions were 30 – 50 % per throughput, and acetaldehyde selectivity was 85 – 95 %. The reaction temperature ranged between 300 and 600 °C depending on the quantity of air. Ethyl acetate, formic acid, acetic acid, and carbon dioxide were byproducts (for more details → Acetaldehyde).

Fragrance Aldehydes. In addition to the production of formaldehyde and acetaldehyde, dehydrogenation and oxidation also are preferred for the synthesis of fragrance aldehydes. A process developed especially for these products permits the catalytic dehydrogenation of $C_5 - C_{14}$ alcohols in the presence of hydrogen and air; it employs copper or silver catalysts, possibly combined with Zn, Cr, Cr_2O_3 [16]. Another catalyst system based on Cu/MgO, produces octanal with a selectivity of 99 % and an octanol conversion of 58 % at 265 – 330 °C [17]. Other catalyst systems described in the literature are Ag/Na_2O on supports [18], mixtures of MnO, NiO on MgO [19], or CuCl and a nitrogen-containing ligand, such as 2,2′-bipyridyl [20]. For further dehydrogenation catalysts see [2, p. 282].

Oxidation of Hydrocarbons. A process developed by Celanese for the oxidation of C_3 and C_4 alkanes [21] produces a complex reaction mixture requiring costly extraction and distillation steps. In this process propane and propane–butane mixtures are reacted in the gas phase at 425 – 460 °C, 0.7 – 0.8 MPa, and with a conversion of about 20 % (with oxygen deficiency). The reaction proceeds according to a radical mechanism. In addition to acetaldehyde (≈20 %) the reaction mixture consists mainly of formaldehyde (≈15 %), methanol (≈19 %), and organic acids (≈11 %). However, the process is outdated technically. The oxidation of methane or ethane also has no practical significance.

Oxidation of Olefins. The most important industrial process for the production of acetaldehyde is the partial oxidation of ethylene in the aqueous phase in the presence of palladium and copper chlorides (Wacker-Hoechst process, → Acetaldehyde, Chap. 4.3.).

Another oxidation process for the preparation of aldehydes from olefins is the acrolein synthesis from propene (→ Acrolein and Methacrolein, Chap. 3.1.).

Miscellaneous Processes. The process involving addition of water to acetylene for the preparation of acetaldehyde has become more or less insignificant compared with the alternative processes based on ethylene or ethanol (→ Acetaldehyde). In Western Europe the last plants were closed in 1980. Apart from the ready availability of the cheaper ethylene and the good selectivity of its conversion, the use of environmentally detrimental mercury sulfate as catalyst has led to the acetylene process becoming essentially obsolete.

The β-hydroxyaldehydes (aldols) and the resulting α,β-unsaturated aldehydes are of commercial significance as starting materials for the production of saturated aldehydes. Examples are the productions of butanal from crotonaldehyde (→ Butanals) and 2-ethylhexanal from 2-ethyl-2-hexenal (see Section 2.4.4).

Laboratory Processes. Only a few examples of the extraordinarily large number of aldehyde syntheses commonly used on a laboratory scale are mentioned here.

The catalytic reduction of acyl chlorides (Rosenmund reduction) is one of the safest and simplest methods of converting carboxylic acids to aldehydes. Mainly Pd – C or Pd – $BaSO_4$ serve as catalysts, if necessary in the presence of a catalyst poison containing sulfur in an aromatic hydrocarbon solvent, such as benzene or toluene. The yields average between 70 and 90 % [1, p. 418], [22].

Other reducing agents are complex borohydrides or aluminum hydrides, such as

bis(triphenylphosphine)copper(I) tetrahydroborate, $[(C_6H_5)_3P]_2CuBH_4$ [23], and lithium tri-*tert*-butyloxyaluminum hydride [24].

Carboxylic acid esters, amides, hydrazides, and nitriles also can be reduced in many ways to the corresponding aldehydes. Most often complex metal hydrido compounds are used as reducing agents.

The oxidative cleavage of olefins with ozone via the ozonides and subsequent reductive decomposition generally take place under extremely mild reaction conditions. With this process, almost quantitive yields are attained [25].

Apart from the classic processes of oxidative glycol cleavage with lead(IV) acetate (Criegee method) [26] and with periodic acid (Malaprade method) [27], there are a number of other oxidizing agents, such as hydrogen peroxide-ruthenium(III) salts [28], manganese dioxide [29], and *N*-iodosuccinimide [30].

When Grignard compounds react with orthoformate esters, aliphatic or aromatic aldehydes are formed [31]. Allylvinyl ethers, which are easily accessible by the reaction of aldehydes with allyl alcohols, rearrange to 4-alkenals (Claisen rearrangement) when heated; the products subsequently can be hydrogenated to the saturated aldehydes [32].

Comprehensive lists of the various preparative methods are given in [1], [2, p. 203], [5, p. 943], [33].

2.4. Individual Saturated $C_5 - C_{13}$ Aldehydes

The higher aldehydes are hydrogenated mainly to alcohols, which are used as solvents or for the production of plasticizers. In addition, they are intermediates for the production of carboxylic acids, amines, and amino acids. They also are used for the synthesis of agricultural chemicals, pharmaceuticals, disinfectants, dyes, etc. In the perfume industry they are used either as such or for the synthesis of odorants such as α-amylcinnamaldehyde.

2.4.1. C_5 Aldehydes

The most important physical properties of the four isomeric C_5 aldehydes, their CAS registry numbers, and their (low) solubilities in water are compiled in Table 1. They are colorless, flammable liquids with intense, characteristic odors, and they exhibit the typical reactions of aliphatic aldehydes. They form azeotropic mixtures with water and are freely soluble in common organic solvents.

Production. Pentanal and 2-methylbutanal are prepared by the hydroformylation of butene [34]:

The ratio of the two products depends on the reaction conditions [1, p. 195].

Isomeric mixtures of pentanal and 2-methylbutanal are often commercial products. Also 2-methylbutanal can be prepared by the reaction of butanal with formaldehyde in the presence of secondary amines with subsequent hydrogenation [35]. 3-Methylbutanal (isovaleraldehyde) is prepared by hydroformylation of isobutene. Small quantities (≈5 %) of 2,2-dimethylpropanal are formed also [36].

2,2-Dimethylpropanal can be obtained by isomerization of 1,1,2-trimethyloxirane at 80 – 170 °C in the presence of $ZnCl_2$-pumice [37].

Another way to manufacture 3-methylbutanal is by the isomerization of 3-methyl-3-butene-1-ol or of a mixture of 3-methyl-3-butene-1-ol and 3-methyl-2-butene-1-ol, prepared from isobutene and formaldehyde. The isomerization catalyst is CuO – ZnO and the reaction temperature is 200 – 250 °C [38].

Uses. The C_5 aldehydes are hydrogenated easily to pentanols (amyl alcohols), which are

used chiefly as solvents and for the production of plasticizers, esters, and xanthogenates (→ Pentanols). Zinc diamyldithiophosphate is an additive for lubricating oils.

Further applications of the C_5 aldehydes are in the oxidation to C_5 acids (→ Carboxylic Acids, Aliphatic) and the preparation of amyl amines by aminating hydrogenation. 2-Methylbutanol (from 2-methylbutanal) can be converted to isoprene over dehydration catalysts at 300 – 350 °C [39] and to isoleucine (→ Amino Acids).

3-Methylbutanal is a starting material for 2,3-dimethyl-2-butene, which in turn is converted to 2,3-dimethylbutane-2,3-diol (pinacol) [40] and to methyl *tert*-butyl ketone (pinacolone) [41]. Pinacolone is a valuable starting material for the synthesis of a number of pesticides.

Pharmaceuticals, such as the active substance butizide [42], are synthesized from 3-methylbutanal and the corresponding acid.

The most important manufacturers of C_5 aldehydes in Western Europe are BASF and Ruhrchemie, and in the United States, Union Carbide.

2.4.2. C_6 Aldehydes

The C_6 aldehydes are colorless, mobile liquids. Their most important physical properties and CAS registry numbers are compiled in Table 1. Hexanal occurs naturally, e.g., in lemon and orange oils.

Production. The preparation of the C_6 aldehydes, of which hexanal, 2-methylpentanal, 2-ethylbutanal, and 3-methylpentanal have medium importance, is carried out almost exclusively by hydroformylation or by aldol condensation. For example, hexanal and 3-methylpentanal are prepared by the hydroformylation of 1-pentene [43] and 2-methyl-1-butene [44], respectively. 2-Methylpentanal is obtained by aldol condensation of propanal, and 2-ethylbutanal by the reaction of butanal with acetaldehyde; in both cases the intermediate unsaturated aldehyde must be hydrogenated subsequently.

Uses. The C_6 aldehydes can easily be hydrogenated or oxidized to the corresponding alcohols or carboxylic acids. 2-Methylpentanal and 3-methylpentanal are starting materials for tranquilizers, such as meprobamate and mebutamate [44], [45]. 2-Methylpentanal also is used for the manufacture of various other products, including agrochemicals, perfumes, and catalysts for cross-linking of polyesters.

2.4.3. C_7 Aldehydes

The C_7 aldehydes are colorless, mobile liquids; all form azeotropic mixtures with water. Heptanal (enanthal) occurs naturally in ginger oil. The most important physical data of the C_7 aldehydes and the CAS registry numbers are given in Table 1.

Production. Heptanal, together with undecanoic acid, is obtained by the pyrolytic cleavage of ricinoleic acid esters [46] or by the hydroformylation of 1-hexene in the presence of modified rhodium catalysts. In the latter case, the straight-chain aldehyde is formed almost exclusively [47]. A minor byproduct is 2-methylhexanal, which can be prepared specifically by reaction of hexanal with formaldehyde followed by hydrogenation [35]. 2,3-Dimethylpentanal is prepared by the hydroformylation of 3-methyl-2-pentene [48] or by the amine-catalyzed reaction of 3-methylpentanal with formaldehyde and subsequent hydrogenation [44]:

Uses. Heptanal is used principally for the preparation of α-amylcinnamaldehyde, a popular fragrance chemical especially in the field of soap perfumery. It is also a starting material for heptanoic acid, esters of which have applications in lubricants. Manufacturers of the aldehyde and/or the acid are Celanese and Monsanto in the United States and ATO Chimie in Western Europe.

2,3-Dimethylpentanal is required for the synthesis of some pharmaceuticals.

2.4.4. C_8 Aldehydes

The physical data and the CAS registry numbers of the most important C_8 aldehydes are presented in Table 1. The C_8 aldehydes form azeotropic mixtures with water, as do most aliphatic aldehydes, and are miscible with the common organic solvents. Octanal occurs naturally in various citrus oils. Of the C_8 aldehydes, octanal, isooctanal, and 2-ethylhexanal have industrial importance.

Production. Octanal (caprylaldehyde) can be obtained by hydroformylation of 1-heptene [49] or by dehydrogenation of octanol [50]. Isooctanal is used as a mixture of isomers and is prepared by hydroformylation of a heptene mixture, the product of codimerization of propene and butene.

The base-catalyzed aldol condensation of butanal leads to 2-ethyl-2-hexenal, which is converted to 2-ethylhexanal by hydrogenation:

2-Propylpentanal can be prepared either by hydroformylation of 3-heptene [51] or in a multistep synthesis from pentanal [52].

Uses. Octanal is employed in the perfume industry for the preparation of synthetic citrus oils and for the synthesis of α-hexylcinnamaldehyde.

Isooctanal is used in the perfume industry and is also catalytically hydrogenated to isooctanol, which is processed further to plasticizers. The aldol reaction of isooctanal with subsequent hydrogenation leads to isohexadecanol, which can be used for the manufacture of synthetic lubricants and hydraulic fluids. 2-Ethylhexanal is used for the manufacture of 2-ethylhexanol (→ 2-Ethylhexanol) and 2-ethylhexanoic acid (→ Carboxylic Acids, Aliphatic). Aminating hydrogenation leads to 2-ethylhexylamines, which are important intermediates in organic syntheses. The condensation of 2-ethylhexanal with aromatic amines results in products that are used as vulcanizing agents and antioxidants for rubber. 2-Propylpentanoic acid (dipropylacetic acid) and its derivatives are prepared from 2-propylpentanal. The sodium salt is an important antiepileptic.

2.4.5. C_9 Aldehydes

Nonanal (pelargonaldehyde) occurs in several natural oils, such as cinnamon oil, lemon grass oil, citrus oil, and rose oils. For physical data and CAS registry numbers see Table 1. The most important C_9 aldehydes are the isomeric mixtures obtained by hydroformylation of commercial C_8 olefin mixtures.

Production. Nonanal is prepared by catalytic dehydrogenation of nonanol [53], by hydroformylation of 1-octene [54], or by reaction of formic acid and nonanoic acid on a titanium dioxide catalyst. Isononanal, prepared on an industrial scale by hydroformylation of commercial diisobutylene, is an isomeric mixture containing about 95 % 3,5,5-trimethylhexanal [55], [56]:

In addition to diisobutylene, other C_8 olefin mixtures are obtained by dimerization of isobutene and butene and are used as feedstock for the production of a number of isononanal mixtures.

Uses. Both nonanal and isononanal are used in the perfume industry. The various isononanals can be converted to isononanol mixtures, which serve as starting materials for the preparation of plasticizers. Upon oxidation isononanoic acid (→ Carboxylic Acids, Aliphatic) is obtained.

Isononanal is an antimicrobial agent [56] and is used for the synthesis of dyestuffs.

2.4.6. C_{10} Aldehydes

Some physical data and the CAS registry numbers are given in Table 1. Decanal is a colorless liquid that is immiscible with water. It has an odor similar to that of orange peel.

Production. Decanal is prepared either by hydroformylation of 1-nonene [57] or by dehydrogenation of 1-decanol on a copper catalyst [17]. 2-Methylnonanal is formed as a byproduct of the hydroformylation of 1-nonene. It can also be prepared by the reaction of nonanal and formaldehyde followed by hydrogenation. Mixtures of *iso*-C_{10} aldehydes are obtained by hydroformylation of commercial C_9 olefins, e.g., tripropylene.

Uses. Besides the use of *iso*-C_{10} aldehyde mixtures as intermediates for isodecanol and isodecanoic acid, C_{10} aldehydes serve primarily as perfumes and fragrance chemicals. The main use of decanal is for citrus tones and for the manufacture of synthetic citrus oils. In addition, the C_{10} aldehydes have value as intermediates in the synthesis of pharmaceuticals and in the polymer and pesticide fields.

2.4.7. C_{11} Aldehydes

Of the C_{11} aldehydes, undecanal and 2-methyldecanal (methyloctylacetaldehyde), possess some commercial value. When pure they are colorless liquids. They have a green, fatty character that blends well with woody and mossy perfume formulations. Undecanal occurs naturally in citrus oils and has a waxy, floral odor. The most important physical data and the CAS registry numbers are presented in Table 1. The aldehydes form azeotropic mixtures with water and are freely soluble in the common organic solvents.

Production. Undecanal is prepared by hydroformylation of decene [57], [58] or by catalytic dehydrogenation of undecanol [17]. Another method is the reduction and subsequent partial hydrogenation of the acid chloride of undecylenic acid, which in turn can be obtained by acidic cleavage of castor oil. 2-Methyldecanal is obtained together with undecanal by the hydroformylation of decene or by the reaction of decanal with formaldehyde and subsequent partial hydrogenation [35], [59]. It is formed also by the Darzens reaction of alkyl chloroacetates with 2-decanone to form glycidic esters, followed by saponification and acidulation [60].

The two isomeric aldehydes can be separated by using the bisulfite adduct [10].

Uses. Undecanal and 2-methyldecanal are used in the perfume industry. Other applications are the syntheses of pharmaceuticals, fungicides, plant growth regulators, bactericides, and disinfectants.

2.4.8. C_{12} Aldehydes

Only dodecanal (lauric aldehyde) occurs naturally in several essential oils, such as rue oil, orange peel oil, and citrus oil. Dodecanal and 2-methylundecanal, because of their pleasant odors, are among the most important toning agents in the aroma industry. The two isomeric aldehydes are colorless liquids, immiscible with water, but freely soluble in most organic solvents. Physical properties and CAS registry numbers are given in Table 1.

Production. Dodecanal is prepared by the catalytic dehydrogenation of dodecanol [61] or by the reduction of the corresponding acid chloride with sodium tetrahydridoborate [62]. 2-Methylundecanal can be obtained by hydroformylation of undecene [58]. Alternatively, the mixture of undecanal and 2-methyldecanal, produced by oxo synthesis, reacts with formaldehyde, followed by partial hydrogenation and distillation [63]. 2-Methylundecanal also is formed from 2-undecanone by the Darzens reaction [60].

2.4.9. C_{13} Aldehydes

The only commercially available C_{13} aldehydes are isomeric mixtures, the composition of which depends primarily on the nature of the olefins that are hydroformylated. Physical properties and CAS registry numbers are given in Table 1.

Production. The C_{12} olefins formed by the oligomerization of butene or propene are converted to the corresponding isomeric tridecanals by hydroformylation. Ziegler α-olefins, olefins from wax cleavage, and olefins produced by metathesis (Shell's SHOP process) also are used as feedstocks.

Table 4. Physical properties of unsaturated aldehydes

	Name	CAS registry number	Formula	M_r	*mp*, °C	*bp* ∗, °C	Density (20 °C), g/cm^3	Refractive index, n_D^{20}	Surface tension (20 °C), mN/m	Viscosity (20 °C), mPa s	Solubility in H_2O at 20 °C, wt%

∗ at 101.3 kPa unless otherwise specified in parentheses.

Uses. Tridecanals are used in the perfume and aroma industries. Their catalytic reduction leads to tridecanols, which are of considerable importance as plasticizer and detergent alcohols. Salts, esters, and other derivatives of isotridecanoic acid, prepared by oxidation of the aldehyde, are of value in the paint and plastics industries.

3. Unsaturated Aldehydes

Acrolein is the most important of the unsaturated aldehydes (→ Acrolein and Methacrolein); crotonaldehyde also is manufactured industrially (→ Crotonaldehyde and Crotonic Acid). Besides these, 2-ethyl-2-hexenal (see Section 3.4.3), citral and citronellal (see Section 3.4.4), and undecylene aldehyde (see Section 3.4.5) are important unsaturated aldehydes.

3.1. Physical Properties

The most important physical data for a number of unsaturated aliphatic aldehydes are summarized in Table 4. The α,β-unsaturated aldehydes in the commercially significant C_3-C_{10} range are liquids. Their boiling points are, without exception, higher than those of the corresponding saturated aldehydes. They resemble the saturated aldehydes in that their viscosities, densities, and refractive indices increase with increasing molecular mass. The compounds are only moderately soluble in water; the solubilities decrease with increasing molecular mass. In common organic solvents, solubilities of the unsaturated aldehydes are high. The lower homologues have a pungent smell and have an irritating effect on mucous membranes. However, the higher unsaturated compounds are often used in the preparation of perfumes and aromas.

Most α,β-unsaturated aldehydes autoxidize easily and tend to polymerize, especially in the presence of base. Small amounts of stabilizers, e.g., hydroquinone, are nearly always added for these reasons.

Many α,β-unsaturated aldehydes form azeotropes with water and other substances. Data for some of these are compiled in Table 5.

Table 5. Azeotropic mixtures of unsaturated aldehydes with water [9]

Aldehyde	*bp* of aldehyde, °C	*bp* of azeotrope, °C	wt% H_2O in azeotrope
Acrolein	53	52.4	2.6
Methacrolein	68	63.6	7.7
Crotonaldehyde	102.4	84	24.8
2-Ethyl-2-butenal	135.3	92.7	38
2-Methyl-2-pentenal	138.2	93.5	40
2-Ethyl-2-hexenal	176	97.6	60.9

Like their saturated counterparts, α,β-unsaturated aldehydes can be unequivocally characterized by IR, ^{1}H NMR, ^{13}C NMR, and by UV/visible spectroscopy.

3.2. Chemical Properties

In addition to the typical reactions of saturated aldehydes already described, the chemical properties of the α,β-unsaturated aldehydes are determined by the conjugation of the olefinic double bond with the carbonyl function. This leads to the formation of 1,2 and 1,4 adducts as a result of nucleophilic addition reactions:

The resulting products play an important role in preparative organic chemistry. A further characteristic reaction of α,β-unsaturated aldehydes is the Diels – Alder conversion, e.g., to alkyl-substituted 2-formyl-2,3-dihydropyranes [64]:

Dienes also can enter into Diels – Alder reactions with unsaturated aldehydes:

Of special importance for the handling of α,β-unsaturated aldehydes is the previously mentioned tendency toward polymerization, which proceeds in a highly exothermic manner in the presence of base.

Each of the two functionalities present in the molecule, the olefinic double bond and the carbonyl group, can be selectively hydrogenated by a suitable choice of catalyst. For example, the olefinic double bond is hydrogenated selectively in the presence of noble-metal catalysts and the carbonyl group in the presence of modified Pt, Ru, or Os catalysts or by a Meerwein – Ponndorf – Verley reaction with aluminum alkoxides to yield the corresponding saturated aldehydes and α,β-unsaturated alcohols, respectively. The saturated alcohols are obtained by hydrogenation over nickel or copper catalysts.

3.3. Production

Although the lower, commercially important α,β-unsaturated aldehydes, such as acrolein, crotonaldehyde, or 2-ethyl-2-hexenal, are obtained exclusively by synthesis, a number of essential oils serve as raw materials for higher homologues, such as for citral or citronellal.

There are two industrial processes for the manufacture of α,β-unsaturated aldehydes:

1) Oxidation of olefins (preparation of acrolein)
2) Dehydration of aldols obtained by aldol condensation of saturated aldehydes (preparation of crotonaldehyde and 2-ethyl-2-hexenal)

In addition there are some special syntheses for the preparation of aldehydes used in the perfume industry such as dehydrogenation of unsaturated alcohols (preparation of citral from geraniol), and reduction of unsaturated acids (undecylenealdehyde from undecylenic acid).

Oxidation of Olefins. The direct oxidation of olefins is industrially important for the manufacture of acrolein from propene. The conversion proceeds at 300 – 480 °C over variously modified Bi – Mo oxide catalysts. The feedstock is a gaseous mixture of propene, air, and water vapor in a molar ratio of about 1 : 10 : 2. Conversion of up to 98 % and acrolein yields of 78 – 92 % are realized. Byproducts include acetaldehyde, acetic acid, and acrylic acid. Commercial acrolein has a purity of 95 – 97 %. The stabilizer, which is added in all processing steps, is usually hydroquinone (for further details → Acrolein and Methacrolein).

Dehydration of Aldols. The β-hydroxyaldehydes (aldols), see Chapter 4 that are formed as intermediates in the aldol reaction are extremely unstable and decompose with loss of water to form α,β-unsaturated aldehydes. Depending on the reaction conditions, the aldol reaction can lead directly to the unsaturated compound. This process is used principally for the synthesis of crotonaldehyde from acetaldehyde, 2-methyl-2-pentenal from propionaldehyde, and 2-ethyl-2-hexenal from butanal.

The aldol condensation of acetaldehyde with catalytic amounts of dilute sodium hydroxide is carried out at 20 – 25 °C. The reaction mixture is treated with acetic acid to stop the reaction. In the subsequent first distillation, water is cleaved from the acetaldol. The selectivity towards crotonaldehyde reaches values up to 95 %.

Not only can two identical aldehyde molecules undergo aldol condensation but also two different aldehyde species can do so. In the latter case a mixture of products usually results. By carefully choosing the reactants and reaction conditions, however, it is possible to obtain the desired compound as the main product. For example, acrolein was formerly prepared by the reaction of formaldehyde with acetaldehyde:

In the same way higher 2-methylenealkanals (2-

alkylacroleins) can be obtained by the reaction of formaldehyde with longer chain aldehydes.

Miscellaneous Processes. For the preparation of some unsaturated aroma aldehydes, the corresponding alcohols are selectively dehydrogenated over copper, copper–zinc, or noble metal catalysts. These processes preferably are carried out under reduced pressure and find application in the manufacture of citral, citronellal, and hydroxycitronellal.

Another method of industrial interest for the synthesis of unsaturated aldehydes is the Claisen rearrangement of allyl vinyl ethers, which are formed as shown in the following reaction scheme [32]:

2-Alkenals are obtained by the reaction of unsaturated alkyl halides with the sodium salts of secondary nitrohydrocarbons, e.g., citral in 80 % yield from 1-halo-3,7-dimethylocta-2,6-diene [65]:

Another possibility is the treatment of acetals with vinyl ethers in the presence of boron trifluoride to give the corresponding β-alkoxyacetals. Under the influence of acids these are converted into α,β-unsaturated aldehydes [66].

For a review of further synthetic methods, see [1], [2].

3.4. Individual Unsaturated C_5–C_{11} Aldehydes

3.4.1. C_5 Alkenals

Of the C_5 alkenals, only 2-methylcrotonaldehyde (tiglic aldehyde) has any significance.The most important physical data and CAS registry numbers of two C_5 alkenals are presented in Table 4. These compounds undergo most of the reactions characteristic of α,β-unsaturated aldehydes.

Production. Several processes for the preparation of tiglic aldehyde are described in the literature; for example, the condensation of acetaldehyde with propanal in the presence of sodium hydroxide [67]; the reaction of 3,4-epoxy-3–methylbutene with palladium acetylacetonate and triphenylphosphine [68]; the isomerization of 2-ethylacrolein [69]; or a two-step synthesis beginning with the catalytic reaction of isoprene, acetic acid, and oxygen to give 2-methyl-1,4-diacetoxy-2-butene, followed by hydrolysis catalyzed by cation-exchange resins [70].

Uses. Tiglic aldehyde is used mainly in the perfume industry. It is also a starting material for the preparation of terpenes, and the *syn*-oxime is used as a sweetener in food.

3.4.2. C_6 Alkenals

The most important physical data and CAS registry numbers for some unsaturated C_6 aldehydes are given in Table 4. The aldehydes are colorless, highly flammable liquids. A number of essential oils contain *trans*-2-hexenal. When diluted, it has an intense odor resembling that of apples.

Production. *trans*-2-Hexenal (leaf aldehyde) is prepared by reaction of butanal with vinyl ether in the presence of boron trifluoride and subsequent treatment of the reaction mixture with dilute sulfuric acid [71] (see next page).

2-Methyl-2-pentenal is formed by aldol condensation of propanal, 2-ethyl-2-butenal by aldol condensation of butanal and acetaldehyde,

and 2-isopropylacrolein by reaction of 3-methylbutanal with formaldehyde [40].

Uses. The perfume and aroma industries use *trans*-2-hexenal as a constituent of floral compositions, 2-methyl-2-pentenal for the manufacture of 2-methylpentanal, and 2-isopropylacrolein as a starting material for the preparation of 2,3-dimethyl-2-butene and pinacol [40]. 2-Ethyl-2-butenal is mainly used for the synthesis of 2-ethylbutyric acid.

3.4.3. C_8 Alkenals

Among the many isomeric C_8 alkenals, *2-ethyl-2-hexenal* is of outstanding economic and technical importance. It is a clear liquid with a characteristic odor and is soluble in practically all organic solvents, although nearly insoluble in water. The most important physical data and the CAS registry number are given in Table 4.

Production. Industrially, 2-ethyl-2-hexenal is prepared by aldol condensation of butanal and subsequent dehydration. The reaction is carried out at 80 – 130 °C and pressures up to 1 MPa in the presence of sodium hydroxide or a basic ion-exchange resin. Many other catalysts are described in the literature [72]. The conversion is over 99 %. The organic phase usually is subjected immediately to further processing to yield either 2-ethylhexanal over a palladium catalyst, or 2-ethyl-1-hexanol over a nickel or copper catalyst [73].

Uses. The main application for 2-ethyl-2-hexenal is the manufacture of 2-ethyl-1-hexanol, the most important plasticizer alcohol with a production capacity (1997) of nearly 10^6 t/a in Western Europe alone and 350 000 t/a in the United States. Condensation products of 2-ethyl-2-hexenal with various aromatic amines have proved to be good vulcanizing agents and antioxidants for rubber.

2-Ethylhexanal, obtainable by selective hydrogenation, is a starting material for the synthesis of the corresponding acid and amines and for the manufacture of pharmaceuticals.

3.4.4. C_{10} Alkenals

The unsaturated C_{10} aldehydes are used preferentially in perfumes and fragrances. Additionally they serve as starting materials for the synthesis of a whole series of terpenoid compounds. The most important representatives are citral a and b (*cis*- and *trans*-3,7-dimethyl-2,6-octadienal) and citronellal (3,7-dimethyl-6-octenal), which occur naturally in many essential oils. They are colorless liquids with odors resembling lemons or balm. Some physical properties and the CAS registry numbers are given in Table 4.

Several industrially established syntheses exist for citral a and b and for citronellal. The isolation from essential oils is now carried out on a large scale only for citronellal. For further details → Flavors and Fragrances.

Uses. Besides the application in the fragrance industry, citral is an intermediate in the vitamin A synthesis and in the preparation of β-ionones [74]. Its acetals, which are relatively stable toward alkali, also are used in the perfume industry. Citronellal is used in small amounts for scenting soaps and detergents. Its principal application is in the preparation of isopulegol, citronellol, and hydroxycitronellal. These compounds also have importance in the fragrance industry.

3.4.5. C_{11} Alkenals

10-Undecenal, undecylene aldehyde, the most important unsaturated C_{11} aldehyde and so far not known to occur naturally, is a colorless liquid with a stifling, flowery odor. For some physical properties and the CAS registry number see Table 4. Undecylene aldehyde is prepared by Rosenmund reduction of undecylenoyl chloride,

which in turn is obtained by cleavage of castor oil. A further possibility is the reaction of undecylenic acid with formic acid over a titanium oxide catalyst. This aldehyde is an important modulating agent in the perfume industry.

4. Hydroxyaldehydes

Of this class of compounds, some β-hydroxyaldehydes in particular are of commercial importance, primarily as intermediates for the preparation of 1,3-diols (see Sections 4.3.1, 4.3.2, and 4.3.4), and α,β-unsaturated aldehydes (see Section 3.3) and their derivatives.

The 2,2-bismethylol compounds of propanal and butanal and the trismethylol compound of acetaldehyde are intermediates in the manufacture of trimethylolethane, trimethylolpropane, and pentaerythritol, respectively (→ Alcohols, Polyhydric).

4.1. Properties

The boiling points of the β-hydroxyaldehydes (aldols) are well above those of the corresponding saturated compounds because of hydrogen bonding. The aldols obtained from lower aldehydes can be vacuum distilled without decomposition only if the salts, present from the condensation reaction, have been completely removed. They decompose upon heating at normal pressure, however [75].

The lower aldols are easily miscible with water and common organic solvents. Some physical data are compiled in Table 6.

For qualitative and quantitative analysis of hydroxyaldehydes, both the hydroxyl and the carbonyl groups can be exploited for the preparation of derivatives.

The chemical behavior of the hydroxyaldehydes is influenced primarily by the ease with which water is cleaved, leading to the formation of α,β-unsaturated aldehydes. This reaction, which is referred to as crotonization, is dependent on the structure of the starting material and on the reaction conditions. It is catalyzed by acids and bases.

Table 6. Physical properties of hydroxyaldehydes

Name	CAS registry number	Formula	M_r	*mp*, °C	*bp* (*p*), °C (kPa)	Density (20 °C), g/cm^3	Refractive index, n_D^{20}
2-Hydroxyethanal (glycol aldehyde)	[*141-46-8*]	$HOCH_2CHO$	60.05	97		1.366 (100 °C)	1.477 (19 °C)
3-Hydroxypropanal	[*2134-29-4*]	$HOCH_2CH_2CHO$	74.05		38 (0.03)		
3-Hydroxybutanal (acetaldol)	[*107-89-1*]	$CH_3CH(OH)CH_2CHO$	88.10		77 (3.0)	1.105	1.4238
4-Hydroxybutanal	[*25714-71-0*]	$HOCH_2(CH_2)_2CHO$	88.10		70 – 72 (1.5)	1.089	1.4450
2,2-Dimethyl-3-hydroxypropanal (hydroxypivaldehyde)	[*597-31-9*]	$HOCH_2C(CH_3)_2CHO$	102.14	ca. 70	ca. 141 (101.3)		
2-Ethyl-3-hydroxyhexanal (butyraldol)	[*496-03-7*]	$CH_3CH_2CH_2CH(OH)CH(C_2H_5)CHO$	144.22		98 – 101 (1.3)	0.9397	1.4426
3,7-Dimethyl-7-hydroxyoctanal (hydroxycitronellal)	[*107-75-5*]	$(CH_3)_2C(OH)(CH_2)_3CH(CH_3)CH_2CHO$	172.27		85 – 87 (0.13)	0.922	1.4488

The catalytic hydrogenation of β-hydroxyaldehydes leads to the formation of 1,3-diols. Important examples are the preparation of propane-1,3-diol from β-hydroxypropanal, 2-ethylhexane-1,3-diol from butyraldol, as well as the previously mentioned preparation of trimethylolethane, trimethylolpropane, and pentaerythritol. The last compound is also formed by reduction with formaldehyde (crossed Cannizzaro reaction).

Monomeric β-hydroxyaldehydes generally are not stable. They react with aldehydes to form so-called aldoxanes (**1**), dimerize to paraldols (**2**), or polymerize.

4.2. Production

Aldol Condensation. The aldol condensation, first mentioned in the literature by A. Wurtz in 1872, can be described in the case of a base-catalyzed reaction by the following mechanism [75]:

The aldol condensation is a reversible reaction. For the catalytic influence of amines and kinetic studies, cf. [76]; for a detailed description of the aldol reaction, cf. [77].

Aldol condensation, which is only possible for aldehydes with at least one α-hydrogen atom, can be catalyzed not only by bases, as shown above, but also by acids. In general, aldols obtained from aldehydes with more than one α-hydrogen atom can be isolated only at low temperature, because they readily lose water to form α,β-unsaturated aldehydes:

If two different aldehydes with α-hydrogen atoms are subjected to aldol addition, all four possible aldol species generally are formed in varying amounts.

Of more importance for industrial purposes are reactions in which only one reactant possesses α-hydrogen atoms; in this case the second reactant is frequently formaldehyde. For the preparation of mono- or polymethylolalkanals by reaction of formaldehyde with alkanals, cf. [75, p. 89] and Section 4.3.4.

These exothermic reactions are mostly carried out in the liquid phase, and aqueous solutions of sodium hydroxide or alkali carbonates usually serve as catalysts. Other catalyst systems have been described, e.g., zinc- or magnesium-containing zeolites [78], alkali hydroxides in combination with phase-transfer catalysts [79], tertiary amines [80], and basic ion exchange resins [81].

Typical byproducts of aldol condensation, apart from the dimeric aldols, aldoxanes, and α,β-unsaturated aldehydes mentioned earlier, are cyclic acetals, Tishchenko esters, etc. This is especially the case for reactions with formaldehyde, in which a reduction of the aldol by a crossed Cannizzaro reaction can occur [82].

G. Wittig, discovered a modification of the classic aldol reaction that involves the treatment of carbonyl compounds with metalated imines. In this case α,β-unsaturated aldehydes are practically the only products. The value of this procedure has been proved in the field of natural products [83], [84].

Miscellaneous Processes. The addition of water to α,β-unsaturated aldehydes yields β-hydroxyaldehydes. This reaction is used industrially for the preparation of 1,3-propanediol (see

Section 4.3.1). 3-Hydroxypropanal also can be obtained by the hydroformylation of ethylene oxide [85]. 4-Hydroxybutanal is obtained by hydroformylation of allyl alcohol [86]. A review of the hydroformylation of unsaturated alcohols to give hydroxyaldehydes has been published [1, p. 212].

If 2,3-dihydro-1,4-pyran is hydrolized, 5-hydroxypentanal is formed; however, it exists in equilibrium with its cyclic hemiacetal [87]. For example, 2-phenyl-2,3-dihydropyran, obtained by Diels – Alder synthesis from acrolein and styrene, can be cleaved by dilute sulfuric acid to give 5-phenyl-5-hydroxypentanal [88].

4.3. Individual Hydroxyaldehydes

4.3.1. 3-Hydroxypropanal

Some physical properties of 3-hydroxypropanal and its CAS registry number are given in Table 6. This compound is the intermediate in the preparation of 1,3-propanediol. It is extremely unstable and normally is not isolated as a pure substance. It can be distilled in high vacuum and characterized as its 2,4-dinitrophenylhydrazone (*mp* 132.5 – 133 °C).

Production. The addition of water to acrolein is the most important process for the production of 3-hydroxypropanal. A ca. 20 % aqueous solution of acrolein is reacted in the presence of a weakly acidic catalyst or an ion exchange resin [89], [90]. The solution can be either hydrogenated directly to 1,3-propanediol or, more advantageously, first subjected to an extraction with isobutanol (→ Propanediols).

Uses. 3-Hydroxypropanal is used exclusively for the production of 1,3-propanediol.

4.3.2. 3-Hydroxybutanal (Acetaldol)

Some physical properties of 3-hydroxybutanal (acetaldol) and the CAS registry number are given in Table 6. This compound is the lowest molecular mass aldol that can be prepared by aldol condensation. Pure monomeric acetaldol boils at 59 – 60 °C (1300 – 1500 Pa). Higher distillation temperatures lead to crotonaldehyde by dehydration and to acetaldehyde by reversal of the condensation. Polymerization of the aldol during its preparation from acetaldehyde can be prevented by addition of hydroquinone or pyrogallol. When pure, acetaldol polymerizes easily to paraldol; stabilization can be achieved by addition of small amounts of water or acetaldehyde.

Production. In the presence of dilute sodium or potassium hydroxide solutions, acetaldehyde is converted to the aldol over a period of several hours in a water-cooled flow tube at 20 – 25 °C. In order to avoid side and secondary reactions, which would result in appreciable resin formation, the reaction is stopped by adding phosphoric or acetic acid when acetaldehyde conversion has reached 60 %. After the unconverted acetaldehyde is separated, a bottom product is obtained that, apart from small amounts of byproducts such as crotonaldehyde, consists of 72 – 73 wt % acetaldol and ca. 18 wt % water [91].

Uses. Acetaldol is used primarily for the preparation of crotonaldehyde. The dehydration takes place during distillation upon addition of some acetic acid. Acetaldol can also be hydrogenated to 1,3-butanediol. The secondary products, butyraldehyde, butanol, and 1,3-butadiene, which at one time were prepared from acetaldol, are now manufactured almost exclusively by other processes.

Acetaldol is used also for the manufacture of substituted quinaldines which, in turn, are valuable starting materials for dyes and pigments [92].

4.3.3. 4-Hydroxybutanal

Some physical properties of 4-hydroxybutanal and its CAS registry number are given in Table 6. Because no conjugated system can be formed, this aldehyde does not tend to split off water, but forms its cyclic hemiacetal, 2-hydroxytetrahydrofuran. Only 4 % of the free hydroxyaldehyde exists in the equilibrium with the hemiacetal. For chemical characterization the compound is transformed into the 2,4-dinitrophenylhydrazone (*mp* 120 – 122 °C).

Production. Allyl alcohol, obtained from propylene oxide, is converted to 4-hydroxybutanal by rhodium-catalyzed hydroformylation. The formation of 3-hydroxy-2-methylpropanal can be minimized by using a large excess of phosphine ligands [86].

Uses. 4-Hydroxybutanal is used for the synthesis of tetrahydrofuran and 1,4-butanediol. This process was commercialized by Arco in 1990.

4.3.4. 2,2-Dimethyl-3-hydroxypropanal (Hydroxypivaldehyde)

2,2-Dimethyl-3-hydroxypropanal (hydroxypivaldehyde) is characterized by the aldehyde group, the primary alcohol group, and the neopentyl configuration.

Although the functional groups provide possibilities for a whole range of reactions, the neopentyl structure is responsible for a noticeable stability toward hydrolysis, heat, and light in many derivatives.

Hydroxypivaldehyde is a colorless liquid that can be distilled in vacuum. Within a short time it dimerizes to a substituted 1,3-dioxane; this reaction is reversible [82], [93]. For some physical properties and the CAS registry number see Table 6.

Production. Hydroxypivaldehyde is prepared by the reaction at ca. 50 °C of isobutyraldehyde and a 30 – 37 % aqueous solution of formaldehyde. The catalysts used are normally aqueous solutions of alkali or alkaline-earth hydroxides [94], but the use of alkali carbonates [95], alcoholic alkali hydroxides [96], tertiary amines [80], and basic ion exchangers [81] also has been described. Because the two starting materials are inexpensive and readily available, other processes for the manufacture of hydroxypivaldehyde have been unable to achieve any industrial importance.

Uses. The most important use of hydroxypivaldehyde is the manufacture of neopentyl glycol, which can be prepared either by a crossed Cannizzaro reaction with formaldehyde or by catalytic hydrogenation (→ Alcohols, Polyhydric, Chap. 2.2.1.). Further products with hydroxypivaldehyde as starting material (cf. [82], [93]) are hydroxypivalic acid neopentyl glycol ester, hydroxypivalic acid, and pantolactone (α-hydroxy-β,β-dimethyl-γ-butyrolactone), which is used in the preparation of pharmaceuticals and vitamins [97].

4.3.5. 2-Ethyl-3-hydroxyhexanal (Butyraldol)

Some physical properties and the CAS registry number are given in Table 6.

As is the case with most aldols, 2-ethyl-3-hydroxyhexanal is not isolated as a pure compound but is converted directly under the prevailing reaction conditions to 2-ethyl-2-hexenal. The aldol can be characterized as the 2,4-dinitrophenylhydrazone derivative (*mp* 172 °C).

Production. 2-Ethyl-3-hydroxyhexanal is prepared primarily by aldol condensation of butanal at 30 °C in the presence of an aqueous sodium hydroxide solution and a phase-transfer catalyst; the reaction is stopped by addition of acetic acid [98].

Other catalysts described in the literature include zeolites containing magnesium or zinc [78] and amines, e.g., tri-, tetra-, or hexamethylenediamine [76].

For the preparation of 2-ethyl-2-hexenal without isolation of the aldol see Chapter 3.4.3.

Uses. 2-Ethyl-3-hydroxyhexanal is used for the preparation of 2-ethyl-2-hexenal, 2-ethylhexanol, 2-ethylhexanal, 2-ethylhexanoic acid, and 2-ethyl-1,3-hexanediol.

4.3.6. 3,7-Dimethyl-7-hydroxyoctanal (Hydroxycitronellal)

Some physical properties and the CAS registry number are given in Table 6.

Hydroxycitronellal is a colorless liquid of low viscosity. So far it has not been found in nature. Its odor is reminiscent of linden flowers and lillies of the valley.

Hydroxycitronellal is used in numerous perfumes. The acetals also occasionally find application as perfumes because of their higher stability toward soap. For preparation and further details, → Flavors and Fragrances.

5. Araliphatic Aldehydes

Araliphatic aldehydes are compounds with the general formula

$$Ar \leftarrow CH_2 \rightarrow_x CHO \ (x \geqq 1)$$

where Ar is some aromatic group, usually phenyl.

Although numerous araliphatic aldehydes occur naturally as components of essential oils, they are usually synthesized.

Araliphatic aldehydes resemble their aliphatic counterparts in that they readily undergo autoxidation and polymerization. Therefore, when stored, air should be excluded, and suitable stabilizers should be added.

Many araliphatic aldehydes and secondary products, such as the corresponding acetals, alcohols, and esters, are established compounds in the perfume industry. They are also starting materials for pharmaceuticals, agricultural chemicals, plasticizers, etc.

5.1. Properties

Physical Properties (see also Table 7). The industrially important araliphatic aldehydes are colorless to pale yellow liquids. They can be distilled, preferably under vacuum, without any appreciable decomposition. All have boiling points above 190 °C at atmospheric pressure, and the densities range between 0.95 and 1.05 g/cm^3. With the exception of phenylacetaldehyde which is slightly soluble in water, the higher araliphatic aldehydes are practically insoluble. The compounds are miscible with alcohols, ethers, and other common organic solvents.

Chemical Properties. Apart from their ease of oxidation, the reactivity of the araliphatic aldehydes is determined by the polarity of the carbonyl group, the resulting acidity of the α-hydrogen atoms (if available), and the aromatic

Table 7. Physical properties of araliphatic aldehydes

Name	CAS registry number	Formula	M_r	*mp*, °C	*bp* *, °C	Density (20 °C), g/cm^3	Refractive index, n_D^{20}
2-Phenylacetaldehyde	[*122-78-1*]	$C_6H_5CH_2CHO$	120.16		195	1.027	1.526

α-Methylcinnamaldehyde	[*101-39-3*]	$C_6H_5CH{=}C(CH_3)CHO$	146.19		150 (10.0)	1.041	1.606 (17 °C)

[a] at 101.3 kPa unless otherwise specified

substituents present in the molecule. These lead to reactions typical of aromatic systems in addition to the reactions of the aldehyde group (see Table 3).

In many cases the aldehyde functionality must be protected before carrying out aromatic electrophilic substitution. However, normally the substituent is already present in the aromatic system before the aldehyde is synthesized.

More important than reactions of the aryl ring are those of the aldehyde group, especially the formation of acetals, which are used in perfumes because of their comparative stability.

In addition to the saturated araliphatic aldehydes, some compounds with olefinic structure, e.g., cinnamaldehyde and α-amylcinnamaldehyde, are important as fragrances. If the aliphatic double bond is conjugated with the carbonyl group, the possibility of 1,4-addition exists (see Section 3.2).

5.2. Production

Most araliphatic aldehydes occur naturally, often widespread, but usually in low concentrations. Therefore, their isolation from natural sources is of relatively little industrial value.

An extraordinarily large number of methods is available for the preparation of araliphatic aldehydes, but only a few are industrially important.

Aldol condensation with subsequent hydrogenation if necessary (Eq. 4):

Hydroformylation of styrenes (Eq. 5):

Isomerization of phenylated oxiranes (Eq. 6):

Friedel-Crafts reactions (Eq. 7):

Darzens glycidic ester synthesis (Eq. 8):

Production of the individual araliphatic aldehydes using these processes is described in the following section.

5.3. Individual Araliphatic Aldehydes

5.3.1. Phenylacetaldehyde

Phenylacetaldehyde, a constituent of numerous essential oils, is a colorless liquid with an odor resembling that of hyacinths and narcissi. Some physical properties and the CAS registry number are given in Table 7.

This extremely reactive compound is highly susceptible to oxidation and polymerization reactions. Alcohols are often added, for example, in perfumery, to stabilize the aldehyde by hemiacetal formation. For a comprehensive review, see [99].

Production. The most important method industrially is the isomerization of styrene oxide (Eq. 6). Ion-exchange resins [100], catalysis by chromium trioxide – tungsten trioxide on graphite [101] or silicon dioxide – aluminum trioxide [102], and thermolysis [103] are recommended for the rearrangement.

Phenylacetaldehyde can also be made by the direct oxidation of styrene in the presence of palladium salts and copper(II) chloride in aqueous solutions of glycol ethers [104].

Other possibilities include the catalytic dehydrogenation of 2-phenylethanol on silver or gold catalysts [105], [106], the hydroformylation of benzyl halides in the presence of dicobalt octacarbonyl and sodium carbonate in acetonitrile [107], and the Darzens glycide ester synthesis from benzaldehyde and alkyl chloroacetates (Eq. 8) [108].

Uses. Phenylacetaldehyde is used in the perfume industry to obtain hyacinth and rose nuances. It also imparts these aromas to tea, tobacco, and coffee (→ Flavors and Fragrances). Further applications include the preparation of pharmaceuticals, insecticides, acaricides, disinfectants, and the use as a rate-controlling additive in the polymerization of polyesters with other monomers.

The reaction of phenylacetaldehyde with ammonia and hydrogen cyanide (Strecker reaction) leads to the formation of phenylalanine, an intermediate for the sweetener aspartame, → Sweeteners. Phenylacetic acid can be obtained by oxidation of the aldehyde.

5.3.2. 4-Methylphenylacetaldehyde

Some physical properties and the CAS registry number are given in Table 7.

4-Methylphenylacetaldehyde has been identified as a constituent of maize oil. The colorless liquid resembles the corresponding unsubstituted aldehyde in that it is extremely reactive and must be stabilized. The compound has a strong floral odor.

Production. The methods of preparation correspond closely to those of phenylacetaldehyde. Thus, the compound can be prepared by glycidic ester synthesis from 4-methylbenzaldehyde and chloroacetate ester [108], by hydroformylation of 4-methylbenzylhalide with $Co_2(CO)_8Na_2CO_3$ in acetonitrile [107], or by oxidation of 4-methylstyrene [109].

Uses. 4-Methylphenylacetaldehyde is used in perfumes, e.g., in soap, in tobacco fragrances, in the preparation of pesticides, etc.

5.3.3. 2-Phenylpropionaldehyde (Hydratropaldehyde)

For some physical properties and the CAS registry number see Table 7.

2-Phenylpropionaldehyde (hydratropaldehyde) has long been established in the fragrance industry. It occurs in many natural products and has a strong fruity smell, reminiscent of hyacinths. Surprisingly, 2-phenylpropanal is much less sensitive to oxidation and polymerization than 2-phenylacetaldehyde. For a review on 2-phenylpropanal and the corresponding alcohol, see [110].

Production. In the last few years a series of new syntheses for 2-phenylpropionaldehyde has been described. However, only a few have achieved industrial significance. The most important is the rhodium-catalyzed hydroformylation of styrene.

In this process $[HCo(CO)_4]$ is unsuitable as a catalyst because then styrene is largely hydrogenated [110], [111]. The use of chiral rhodium

complexes leads to the formation of optically active aldehydes when prochiral olefins, such as styrene, are used. Asymmetric hydroformylation, however, has so far found no industrial application because of insufficient purity of the enantiomers [112].

Other synthetic methods are the gas-phase oxidation of α-methylstyrene on Cu, Bi – Mo – P – SiO_2 [113], or Pd salt catalysts [114], the rearrangement of expoxidized α-methylstyrene [100–103], and the dehydrogenation of 2-phenyl-1-propanol on Ag catalysts at reaction temperatures of ca. 600 °C [105], [106].

Uses. 2-Phenylpropanal and its hydrogenation product, 2-phenylpropanol, are used in perfumes. The aldehyde also is a valuable starting material for a series of pharmaceuticals and pesticides, and it serves in the plastics field as a stabilizer, catalyst, and hardener.

5.3.4. 3-Phenylpropionaldehyde (Dihydrocinnamaldehyde)

Some physical properties and the CAS registry number are given in Table 7.

3-Phenylpropionaldehyde resembles most araliphatic aldehydes in that it is only storable to a limited extent. It is a colorless liquid with a pronounced cinnamon aroma. The aldehyde occurs naturally in Ceylon cinnamon oil. For a review, see [110].

Production. The most common preparative process for 3-phenylpropanal is the partial hydrogenation of cinnamaldehyde [115].

The 3-phenylpropanal that is formed during the hydroformylation of styrene can be separated from the isomeric 2-phenylpropanal as the bisulfite adduct [10]. The Rosenmund reduction of dihydrocinnamoyl chloride in the presence of Pd/$BaSO_4$ gives good yields of the aldehyde [116]. The reaction of 2-propen-1-ol and phenylmercury chloride with $CuCl_2$ and $LiPdCl_4$ catalysts in methanol, and the reaction of phenyl bromide and allyl alcohol in the presence of $PdCl_2$ and $NaHCO_3$ in nonpolar solvents also lead to the formation of 3-phenylpropanal [117]. A review of further synthetic methods is given in [110].

Uses. The uses of 3-phenylpropanal correspond in general to those of 2-phenylpropanal.

5.3.5. 2-(4-Isobutylphenyl)propionaldehyde

Some physical properties and the CAS registry number are given in Table 7.

2-(4-Isobutylphenyl)propionaldehyde is a colorless, mobile liquid with a pleasant odor.

Production. Numerous methods are known for the synthesis of 2-(4-isobutylphenyl)propionaldehyde. It can be prepared by reaction of *p*-isobutylacetophenone with methyl chloroacetate using sodium methoxide as catalyst, followed by reaction of the glycidic ester with BF_3 to give 2-hydroxy-3-(4-isobutylphenyl)-3-butenoic acid ester, which is subsequently treated with mineral acid [118]:

A variant of the process is the hydrolysis of the intermediately formed glycidic ester with al-

kali to give the corresponding salt of glycidic acid, which is then decarboxylated [119].

2-(4-Isobutylphenyl)propanal also is formed by isomerization of 2-(4-isobutylphenyl)-2-methyloxirane on Al_2O_3-SiO_2 [120] or anhydrous $ZnCl_2$ [121], by reaction of 1-(4-isobutylphenyl)-1-chloroethane with dimethylformamide in the presence of Li or Na in tetrahydrofuran [122], and in good yields by Rh- or Co-catalyzed hydroformylation of *p*-isobutylstyrene [123].

Uses. Unlike many araliphatic aldehydes 2-(4-isobutylphenyl)propionaldehyde has no significance in the perfume industry. It is used exclusively for the preparation of the antirheumatic agent Ibuprofen, 2-(4-isobutylphenyl)propionic acid (→ Anti-inflammatory–Antirheumatic Drugs).

5.3.6. 3-(4-Isopropylphenyl)-2-methylpropanal (Cyclamenaldehyde)

Cyclamenaldehyde, 2-methyl-3-(4-isopropylphenyl)propionaldehyde, is one of the fragrance and aroma substances of above average importance, → Flavors and Fragrances. The normal commercial racemate is a colorless to pale yellow liquid. The aldehyde is reviewed in [124].

Some physical properties and the CAS registry number are given in Table 7.

In addition to its use in numerous perfume compositions, cyclamenaldehyde is an intermediate for the preparation of fungicides and fungistatic substances [125].

5.3.7. 3-(4-*tert*-Butylphenyl)-2-methylpropionaldehyde (Lilial)

3-(4-*tert*-Butylphenyl)-2-methylpropanal (→ Flavors and Fragrances), a colorless to pale yellow liquid, as yet has not been found in nature. It has a higher stability than the homologous cyclamenaldehyde and therefore is used as scent in soaps. Some physical data and the CAS registry number are summarized in Table 7. A monograph on the compound has been published [126]. More than 1000 t/a of the aldehyde is produced.

Production. The aldehyde is produced industrially almost solely by aldol condensation of 4-*tert*-butylbenzaldehyde and propionaldehyde to give 4-*tert*-butyl-α-methylcinnamaldehyde, which can be hydrogenated selectively on noble metal catalysts such as Pd, Rh, Pd – Pr_2O_3 on Al_2O_3 [127], [128], or on modified cobalt catalysts [129], [130]. The aldol condensation and the hydrogenation can be carried out in one step in the presence of a hydrogenation catalyst [131].

The Friedel – Crafts reaction of 4-*tert*-butylbenzene with methacrolein or methacrolein diacetate (Eq. 7, in page 23) proceeds in an analogous manner to the preparation of cyclamenaldehyde [132].

Further possibilities are the Rh-catalyzed hydroformylation of 1-(4-*tert*-butylphenyl)-1-methoxypropene and subsequent partial hydrogenation [133], the palladium salt catalyzed reaction of 4-*tert*-butylphenylhalide with methallylalcohol [134], and the dehydrogenation of 3-(4-*tert*-butylphenyl)-2-methylpropanol on silver catalysts [105], [106].

Uses. In addition to its applications in the perfume and aroma industry, lilial is used mainly for the synthesis of substituted 3-(4-*tert*-butylphenyl)-2-methylpropylamines, a new class of substances with fungicidal properties [125]. These compounds are effective against mildew in barley and wheat.

5.3.8. Cinnamaldehyde (3-Phenyl-2-propenal)

Cinnamaldehyde (for more details → Flavors and Fragrances), the simplest unsaturated ar-

aliphatic aldehyde, is produced in considerable quantities. It has outstanding significance as a fragrance. The *trans* isomer is the major product of industrial manufacturing processes and is the predominant naturally occurring one. Some physical properties and the CAS registry number are given in Table 7.

For the *synthesis* only the base-catalyzed condensation of benzaldehyde with acetaldehyde has been adopted on an industrial scale.

Uses. In addition to its application as a fragrance, it is used for the preparation of corrosion inhibitors, as a polymerization inhibitor for conjugated dienes, and for the coating of metals [145].

Partial hydrogenation or oxidation of cinnamaldehyde give 3-phenylpropanal or cinnamic acid, respectively.

5.3.9. α-Alkylcinnamaldehydes (2-Alkyl-3-phenyl-2-propenals)

The most important of the α-alkylcinnamaldehydes are α-amyl-, α-hexyl-, and α-methylcinnamaldehyde (→ Flavors and Fragrances).

R = CH_3, C_5H_{11}, or C_6H_{13}

Some physical properties and the CAS registry numbers are given in Table 7. The aldehydes are synthesized, analogously to cinnamaldehyde, by aldol condensation. In addition to the considerable use for these compounds in the perfume industry, they are starting materials for their hydrogenated derivatives, and for the preparation of pharmaceuticals and agrochemicals.

6. Dialdehydes

Dialdehydes, compounds bearing two formyl moieties, are of significant commercial interest. Dialdehydes are used as disinfectants, corrosion inhibitors in oil recovery, leather tanning agents, hydrophobizing agents for paper, wallpaper and textiles, biological fixatives, and cross-linkers in thermosetting resins [135]. Glyoxal (ethanedial) is the simplest possible and commercially most important dialdehyde (→ Glyoxal). Because of their bifunctionality dialdehydes are potential intermediates for the synthesis of diols, dicarboxylic acids and diamines, and as monomers for the synthesis of polyesters, polyamides, and polyurethanes. Because of their reactivity, dialdehydes are often converted directly to such more stable derivatives.

6.1. Properties

Physical data of some dialdehydes are compiled in Table 8. Glyoxal has a melting point of 15 °C and boils at 50.4 °C. Propanedial exists as the isomeric 3-hydroxyacrolein. Therefore it is a solid with a melting point of 72 – 74 °C. The higher α,ω-dialdehydes are high boiling liquids. The boiling points of the isomeric branched dialdehydes are lower than those of the linear α,ω-dialdehydes.

Dialdehydes have an intrinsic tendency to undergo polymerization. For long chain α,ω-dialdehydes cyclopolymerization reactions are known [136]. Anhydrous glyoxal polymerizes readily to complex polymeric structures. The monomer can be recovered from this polymer by heating in the presence of phosphorus pentoxide. Similar to formaldehyde, glyoxal reacts with water in a highly exothermic reaction to yield a mixture of linear and cyclic oligomers. In aqueous solution, higher dialdehydes form cyclic hemiacetals.

6.2. Production

Although many syntheses of dialdehydes are described in the patent literature, only a few are of commercial interest, mainly due to lack of selectivity. The most important processes for the preparation of saturated aliphatic and cycloaliphatic dialdehydes are:

– Oxidation of ethylene glycol (→ Glyoxal, Chap. 4.)

Table 8. Physical properties of aliphatic and alicyclic dialdehydes

	Name	CAS registry number	Formula	M_r	*mp*, °C	*bp*∗∗, °C (*p*)	Density (20 °C), g/cm^3	Refractive index n_D^{20}

∗∗ at 101.3 kPa unless otherwise specified in parentheses.

– Oxidation of acetaldehyde (→ Glyoxal, Chap. 4.)
– Hydroformylation of dienes
– Oxidative ring opening of cycloalkenes
– Addition of methyl vinyl ether to acrolein (glutardialdehyde)

Hydroformylation of dienes yields different products depending on the structure of the diene and the catalyst applied [1], [3]. Conjugated dienes such as 1,3-butadiene yield saturated monoaldehydes or monoalcohols if unmodified cobalt or rhodium catalysts are used. Initially the single addition of CO/H_2 yields the unsaturated monoaldehyde. The hydroformylation of the unsaturated aldehyde than competes with hydrogenation and isomerization of the double bond. Patent literature describes the bis-hydroformylation of 1,3-butadiene to 1,6-hexanedialdehyde with special modified rhodium catalysts, but commercial realization remains questionable [137].

Nonconjugated dienes tend to isomerize to the thermodynamically more stable α,β-unsaturated aldehydes after single addition of CO/H_2 [3]. Therefore, especially nonconjugated dienes with widely separated ($> C_6$), preferably terminal double bonds are useful for synthesis of dialdehydes by hydroformylation.

Oxidative Ring Opening of Cycloalkenes. In the presence of catalysts, e.g. tungstic acid, cycloalkenes react with hydrogen peroxide via formation of the corresponding epoxides to give linear α,ω-dialdehydes [138].

In some cases the addition of boron compounds facilitates the reaction. Oxidation of cycloalkenes in the gas phase has also been described [139].

Miscellaneous Processes. Similar to the formation of monoaldehydes by dehydrogenation, the dehydrogenation of diols yields dialdehydes. Other routes are the ozonization of cycloalkenes and the dimerization of unsaturated aldehydes [3], [140]. Hydroformylation of unsaturated acetals gives the corresponding dialdehydes.

6.3. Individual Dialdehydes

6.3.1. Succinaldehyde (1,4-Butanedial)

Some physical properties of succinaldehyde and its CAS registry number are given in Table 8. To avoid spontaneous polymerization of anhydrous succinaldehyde, it is best stored as a cyclic acetal, e.g., 2,5-dimethoxytetrahydrofuran. Aqueous solutions consist mainly of the cyclic hemiacetal 2,5-dihydroxytetrahydrofuran.

Production. Succinaldehyde is prepared by various routes, e.g., reaction of chlorine with tetrahydrofuran and subsequent acid hydrolysis. Hydroformylation of acrolein acetals (mostly cyclic) yields a mixture of 2- and 3-(1,3-dioxan-2-yl)propanal. Hydrolysis of the latter forms 1,4-butanedial [141].

Due to the similar chemical properties, succinaldehyde has been replaced extensively by glutardialdehyde, diminishing its commercial importance significantly.

Uses. Succinaldehyde is used as disinfectant, biological fixative, and cross-linker in thermosetting resins.

6.3.2. Glutardialdehyde (1,5-Pentanedial)

Some physical properties of glutardialdehyde and its CAS registry number are compiled in Table 8. Glutardialdehyde is the most important dialdehyde besides glyoxal. Due to its high reactivity glutardialdehyde is sold as a 25 or 50 wt % aqueous solution or as its bis(sodium bisulfite) adduct.

Production. Glutardialdehyde is produced by gas-phase oxidation of cyclopentene or by Diels – Alder reaction of acrolein with methyl vinyl ether [139], [142]. The latter yields 3,4-dihydro-2-methoxy-2*H*-pyran [*4454-05-1*], acidic hydrolysis of which leads to glutardialdehyde.

In both cases the dialdehyde is recovered from the reaction mixture by multistage extraction with water.

Uses. Glutardialdehyde is used mainly for leather tanning, as a disinfectant and sterilizer, as a biocide in oil recovery, and in the paper and textile industries to improve wet strength and dimensional stability of fibers.

6.3.3. TCD Dialdehyde

Some physical properties and the CAS registry number of TCD dialdehyde (isomeric mixture), 3(4),8(9)-bis(formyl)tricyclo[5.2.1.0^{2,6}]decane, are given in Table 8. Like other dialdehydes TCD dialdehyde is not very stable and has a significant tendency for polymerization. Distillation under reduced pressure is possible. In practice the dialdehyde is not stored but converted immediately to more stable derivatives.

Production. TCD dialdehyde is produced in up to 95 % yield by hydroformylation of dicyclopentadiene on rhodium catalysts. To achieve bis-hydroformylation, a high pressure of synthesis gas is required (150 – 250 bar) [143].

If unmodified cobalt catalysts are used the dialdehyde is mostly hydrogenated to TCD diol, 3(4), 8(9)-bis(hydroxymethyl)tricyclo[5.2.1.0 ^{2,6}]decane, and TCD monoaldehyde monoalcohol. At low synthesis gas pressures, mainly the monoaldehyde is formed.

Uses. TCD dialdehyde is used for the production of the corresponding diamine, dicarboxylic acid, and diol. These compounds are used as monomers for production of poylesters, polyamides, and polyurethanes. Also some applications in the field of flavors and fragrances or dental materials are known [144].

7. Acetals

Acetals can be represented by the general formula

where R can be either hydrogen or some aliphatic, aromatic, or heterocyclic group. In contrast to the hydrates (R′ = H), which normally cannot be isolated, the acetals are generally stable compounds.

Cyclic acetals can be prepared by reaction of aldehydes with diols; 1,2- and 1,3-diols are the most common.

1,3-Dioxolanes

1,3-Dioxanes

For the lower acetal homologues, trivial names are frequently used, e.g., methylal for dimethoxymethane. Because of their stability toward alkali, acetals are used as soap perfume oils. The scents of the acetals are somewhat different and less distinct than those of the corresponding aldehydes.

Acetals are found in wine and other alcoholic drinks. Piperonal, a raw material for aroma compositions, and numerous alkaloids such as piperine, a main alkaloid of black pepper, or berberine, which is found mainly in barberry roots, possess a methylenedioxy group.

7.1. Properties

Physical Properties. The lower acetals are colorless, mobile liquids, with boiling points distinctly higher than those of the corresponding aldehydes. Their solubilities in water decrease rapidly with increasing molecular mass. They have good solubilities in alcohols, ethers, and other common solvents. The most important physical data and the CAS registry numbers of some acetals are presented in Table 9.

As a rule acetals can be purified by distillation. The distillation residue must be handled with extreme care because, as a result of the ether structure of the acetals, it can contain explosive peroxides. For the same reason care should be taken when storing acetals.

Chemical Properties. Acetals are extremely stable toward base, but are hydrolyzed easily by acid. Because of these properties, the acetals provide interesting possibilities for synthesis, especially in carbohydrate chemistry.

In contrast to the aliphatic alkanals, their acetals are extremely resistant to most reducing and oxidizing agents. This is only true to a limited extent for the acetals of aromatic aldehydes, however.

Among the factors that influence the rate of hydrolysis in acids is the structure of the acetal; all the cyclic acetals are more stable than the open-chain species. Difficulties arise during hydrolysis when the aldehyde group is very reactive; secondary reactions, such as aldol condensation, occur.

Acetals can be transacetalized by other carbonyl compounds or alcohols:

The thermal cleavage of an acetal leads to a vinyl ether and an alcohol:

If R′ is an allyl group, Claisen rearrangement to the corresponding unsaturated aldehyde takes place during the thermal cleavage (see page 16).

The cleavage of 4,4-dimethyl-1,3-dioxane, a cyclic acetal, prepared by the Prins reaction of isobutene with formaldehyde (see below), is of industrial importance for the manufacture of isoprene. The dioxane is split at 240 – 400 °C on H_3PO_4/C or $Ca_3(PO_4)_2$ catalysts in the presence of water:

Both BF_3 or $ZnCl_2$ catalyze the reactions of acetals with vinyl ethers to give β-alkoxyacetals, which are converted to the corresponding α,β-unsaturated aldehydes upon treatment with acetic acid:

Table 9. Physical properties of some acetals

Name	CAS registry number	Formula	M_r	*mp*, °C	*bp*, °C	Density (20 °C), g/m^3	Refractive index, n_D^{23}
Formaldehyde dimethyl acetal (methylal)	[*109-87-5*]	$CH_2(OCH_3)_2$	76.09	− 104.8	45.5	0.8593	1.3513
Formaldehyde diethyl acetal (ethylal)	[*462-95-3*]	$CH_2(OCH_2CH_3)_2$	104.15	− 66.5	89	0.8319	1.3748
Acetaldehyde dimethyl acetal (1,1-dimethoxyethane)	[*534-15-6*]	$CH_3CH(CH_3)_2$	90.12	− 113.2	64.5	0.8502	1.3668
Acetaldehyde diethyl acetal (1,1-diethoxyethane)	[*105-57-7*]	$CH_3CH(OCH_2CH_3)_2$	118.18		103.2	0.8314	1.3834
Propionaldehyde dimethyl acetal (1,1-dimethoxypropane)	[*4744-10-9*]	$CH_3CH_2CH(OCH_3)_2$	101.15		84 – 86	0.8649

Pentanal diethyl acetal (1,1-diethoxypentane)	[*3658-79-5*]	$CH_3(CH_2)_3CH(OCH_2CH_3)_2$	160.25		162.5 – 163.5	0.8304	1.4021
Hexanal diethyl acetal (1,1-diethoxyhexane)	[*3658-93-3*]	$CH_3(CH_2)_4CH(OCH_2CH_3)_2$	174.28		155 – 158		
1,3-Dioxolane	[*646-06-0*]		74.08	− 95	78	1.0600	1.3974
1,3-Dioxane	[*505-22-6*]		88.12	− 42	105 (100.6)	1.0342	1.4165
2-Methyl-1,3-dioxolane	[*497-26-7*]		88.12		81 – 82	0.9811	1.4035
2-Methyl-1,3-dioxane	[*626-68-6*]		102.13		108.5 – 109.5 (99.3)	0.9701	1.4139

7.2. Production

The primary process for the preparation of acetals is the reaction of an aldehyde with an alcohol. As a rule, a unstable hemiacetal is formed as an intermediate:

Because the reaction is an equilibrium process, the water must be removed by azeotropic distillation or by the addition of water-adsorbing agents, e.g., molecular sieves, in order to improve the yield. Cyclic acetals are generally obtained in better yield than open-chain acetals. As catalysts, anhydrous sulfuric acid or *p*-toluene sulfonic acid are normally used, although other inorganic acids, oxalic or adipic acid, or ion-exchange resins or molecular sieves also can be employed.

During the acetalization of saturated aliphatic aldehydes that contain an α-hydrogen atom, 1-alkenylethers can be formed, if the reaction temperature is too high:

In accordance with a process developed by L. Claisen acetals are formed in good yields from most aldehydes by treating them with orthoformates, mainly the methyl and ethyl esters. Strong acids are normally used as catalysts:

Acetals can also be obtained by reaction of acetylene with alcohols, by addition of alcohol to vinyl ethers, and by treatment of geminal dihalides with alkoxides. Aldehydes and oxiranes form 1,3-dioxolanes, and pyrocatechols and dichloromethane form 1,3-benzodioxoles.

Of industrial importance is the acid-catalyzed reaction of olefins with formaldehyde to give 1,3-dioxanes (Prins reaction):

The reaction is carried out at 55 – 75 °C with an excess of formaldehyde.

The reaction of olefins with alcohols under hydroformylation conditions using, for example, phase-transfer catalysts also leads to the formation of acetals [146].

Acetaldehyde dimethyl acetal is obtained at 200 °C from methanol and synthesis gas under catalytic conditions [147]. The methanol conversion is about 60 % with a selectivity of 80 – 85 %. Byproducts are mainly acetaldehyde and ethyl acetate.

Vinyl esters can be converted to acetals by reaction with alcohols in the presence of palladium chloride catalyst:

For further methods of synthesis and a review of the reactions of acetals, see [1, p. 615], [148].

7.3. Uses

Acetals frequently are used in preparative chemistry to protect aldehyde functions. The acetals of lower aldehydes, e.g., formaldehyde dimethyl acetal (methylal), serve as solvents for cellulose and cellulose derivatives.

Although acetals have a somewhat weaker fragrance than the corresponding aldehydes, they are used for preparing soap perfume oils, especially because of their stability toward alkali. This applies both for open-chain as well as for cyclic acetals [149].

In polymer chemistry acetals are used for the preparation of epoxy resins [150] and aqueous dispersions [151]. The acetals of polymeric alcohols, such as polyvinyl alcohol, are employed as interlayers in safety glasses. Acetals are also

used for the synthesis of pharmaceuticals, insecticides [152], fertilizers [153], and as constituents of sun lotions [154].

Substituted 1,3-dioxanes are intermediates in the synthesis of conjugated dienes. The IFP (Institut Français du Pétrole) process for the production of isoprene is the most important example [155].

8. Quality Control

The actual method used for the determination of quality primarily depends on the further processing and the special properties of the individual products. In general, high purity of the aldehydes is required.

The composition is analyzed by gas chromatography (cf. Chap. 9). In addition, the following characteristic data usually are determined:

1) Density at 20 °C (DIN 51 757, ASTM D 1298)
2) Refractive index n_D^{20} (DIN 51 423, Bl. 2, ASTM D 1747)
3) Acid value (DIN 53 402, ASTM D 1613)
4) Hazen color index (APHA) (DIN ISO 6271, ASTM D 1209)
5) Boiling range at 101.3 kPa (DIN ISO 51 777, ASTM D 1364)
6) Water content by the Karl Fischer method (methanol-free reagents and solvents)

The following data also can be useful:

1) Carbonyl value (DIN 53 173, ASTM D 2192)
2) Hydroxy value (DIN 53 240, ASTM E 222)
3) Viscosity at 20 °C (DIN 51 757, ASTM D 4052)
4) Iodine number (determination by the Kaufmann method DGF C-V116; for unsaturated aldehydes)

Safety data, such as TLV and MAK values, acute and chronic toxicology data, flash points (DIN 51755, ASTM D 56 or DIN 51758, ASTM D 93), ignition temperatures (DIN 51794, ASTM D 2155), vapor pressures, and solubilities in water, are important under certain circumstances, e.g., for classification and handling of the products during storage and transportation.

9. Analysis

Aldehydes are mainly analyzed by chromatographic and spectroscopic techniques; chemical detection methods also are used.

The most important qualitative and quantitative analytical procedure in industry is *gas chromatography.* The optimum procedure, i.e., filling of the column, carrier gas, detector, etc., depends on the nature of the sample and the individual requirements.

The majority of GC analyses of aldehydes are performed on capillary columns. Packed columns are also still used. Columns with a length of 1 – 3 m and an inner diameter of 2 – 4 mm, and capillary columns (25 – 100 m) with various polar stationary liquids can be used. The most frequently employed support materials are calcinated diatomaceous earths.

The amount of sample that is injected is 0.1 – 0.5 µL for capillary columns with flow separation and 1 – 3 µL for packed columns. In some cases it is advisable to convert the products into derivatives before analysis. Carrier gases which have proven suitable are N_2, He, and H_2. If hydrogen is used, particular care must be taken that both the injection system and the column are free from catalyst deposits; otherwise the aldehydes easily could be hydrogenated. For compounds with particularly low thermal stability, such as the aldols, the sample is added directly into the separating column.

The 2,4-dinitrophenylhydrazones generally are used in *liquid chromatography.* UV detectors serve to identify the constituents of the sample.

For the *chemical identification* of aldehydes, crystalline derivatives of low solubility are used, e.g., 2,4-dinitrophenylhydrazones, semicarbazones, oximes, sodium hydrogen sulfite adducts, and dimedon condensation products. For qualitative detection the reducing properties of the aldehydes (e.g., reaction with Fehling's solution or Tollen's silver nitrate solution) and numerous color reactions can be used. The reducing properties of the aldehydes are not specific, however.

Aldehydes can be detected qualitatively and identified by IR, ^{1}H NMR, and ^{13}C NMR spectroscopy. In IR spectroscopy saturated aldehydes can be characterized by the intensive CO stretching vibration in the range 1740 –

1720 cm^{-1}, and α,β-unsaturated compounds by the absorption at 1705 – 1685 cm^{-1}. The absorption is shifted to lower frequencies for conjugated, unsaturated compounds.

In the ^1H NMR spectrum the formyl H is found at 9.4 – 9.8 ppm in saturated aliphatic aldehydes; the coupling constant is 0 – 3 Hz for the H-C-CHO system. The corresponding values for unsaturated compounds are 9.3 – 10.2 ppm; the coupling constants for the system R–CH=CH–CHO are strongly dependent on whether the compound has E or Z configuration and which substituents are present.

For further details of the analysis of aldehydes see [156].

10. Storage, Transportation, and Environmental Regulations

For storage and transportion, containers of stainless steel normally are used. Vessels lined with polyethylene or other coatings are also suitable. For aldehydes that enter the market as solutions, such as formaldehyde, glyoxal, or glutaraldehyde, aluminum vessels or containers of standard steel should not be used, because the acids formed by autoxidation are corrosive, and the corrosion products can cause discoloration of the aldehyde.

Aldehydes are normally stored under a nitrogen atmosphere. Antioxidants and stabilizers are added to prevent autoxidation.

The formation of cyclic 2,4,6-trialkyl-1,3,5-trioxane trimers is catalyzed by the presence of strong protic and Lewis acids. The trimerization tendency of aldehydes occasionally increases at lower temperatures, so that some compounds cannot be stored over long periods at temperatures under 20 °C without stabilization [1, p. 651].

Some α,β-unsaturated aldehydes, such as acrolein, methacrolein, and crotonaldehyde, can react violently if handled incorrectly in the presence of air or oxygen or some other, in particular, alkaline compound.

Because of their health hazards, saturated and unsaturated aliphatic aldehydes, especially the lower members, should be handled only if special safety precautions are taken. Necessary measures can be found in the regulations on dangerous materials and in the directions on accident prevention, guidelines, leaflets, etc., published by the confederation of trade associations.

For the economically important aldehydes numerous transport regulations and legal directions exist (IMO, IATA, RID, ADR, etc.). The classification of a special aldehyde depends on its specific properties such as flash point, boiling point, solubility in water, toxicity, and ignition temperature.

Because the aldehydes sometimes have a very unpleasant and intense odor, special environmental measures are necessary during manufacture, storage, and dispatch. The aldehyde-containing off-gas from the production normally is drawn off centrally and burned. The wastewaters are treated chemically and biologically.

11. Economic Aspects

The most important process for the manufacturing of aldehydes with more than two carbon atoms is the oxo synthesis. In 1994 total worldwide capacity was 7.2×10^6 t/a with further capacities of $(0.5 – 1.0) \times 10^6$ t/a planned or under construction. Table 10 lists oxo capacities by region for 1984 and 1994.

Table 10. Oxo capacities by region (in 10^6 t/a)

	1984	1994
Western Europe	2.5	2.4
United States	1.4	2.4
Japan	0.5	0.8
Others	0.6	1.6
Total	5.0	7.2

The most important secondary product of butyraldehyde is 2-ethylhexanol, with worldwide capacities of 2.6×10^6 t/a in 1996. The consumption of various oxo chemicals in Western Europe, the United States, and Japan is compiled in Table 11.

For the most important aldehydes used in the perfume industry, few production data are available. Estimated production for the most important fragrance aldehydes are as follows: cinnamaldehyde 1500 t/a, lilial 1500 t/a, hydroxycitronellal 1500 t/a, α-hexylcinnamaldehyde 1000 t/a, α-amylcinnamaldehyde 800 t/a, citral 500 t/a, citronellal 400 t/a, and cyclamenaldehyde 350 t/a.

Table 11. Consumption of oxo chemicals by region (in 10^3 t/a)

	Western Europe		United States		Japan	
	1993	1998	1993	1998	1993	1998

Aldols → Aldehydes, Aliphatic and Araliphatic
Alfol Process → Fatty Alcohols
Algin → Polysaccharides
Alkali and Chlorine Products → Chlorine
Alkali and Chlorine Products → Sodium Hydroxide

Alkaloids

Many of the alkaloids described under this keyword possess pharmaceutical importance. For more details on their use in chemotherapy, see the corresponding keywords.

1. Introduction

The typical alkaloid is an alkaline compound having one or more heterocyclic nitrogen atoms. It is found in nature, usually in plants. Some of the alkaloids show pronounced physiological action, and several alkaloids, e.g., reserpine, quinine, and morphine, have been used in medicine. It is no longer customary to include the purine and pyrimidine bases in the alkaloid group.

The alkaloids usually occur in the form of salts with organic acids (oxalic, acetic, malic, meconic, or succinic acid). Therefore these compounds most often have been isolated as free bases by treatment of the source plants with an alkali solution. Traditionally, the alkaloids have been purified by recrystallization of the free base or a salt, but chromatographic methods are also used frequently. For detection of alkaloids the Mayer reagent (potassium mercuric iodide), Wagner reagent (iodine-potassium iodide), Dragendorff reagent (potassium bismuth iodide), Sonnenschein reagent (phosphomolybdic acid), and Scheibler reagent (phosphotungstic acid) are used. These are called alkaloid reagents.

Structure determination has been carried out by the usual chemical and physicochemical methods. The frequently used chemical methods are the following: zinc distillation, dehydrogenation on palladium or selenium, and alkali fusion to determine the basic skeleton and Hofmann degradation, Emde degradation, and von Braun degradation to elucidate the nitrogen part of the molecule. In addition, controlled oxidation and reduction processes have been used to determine some functional groups. Today,

physicochemical techniques are the best way to elucidate the structure of an alkaloid. The following methods should be available to an alkaloid laboratory: ultraviolet and infrared spectroscopy, proton and carbon-13 nuclear magnetic resonance (NMR), optical rotatory dispersion (ORD), circular dichroism (CD), mass spectrometry, and X-ray analysis. In the near future, computer analysis systems involving all these physicochemical methods are expected to increase the effectiveness of structural determination.

Biosynthesis. Alkaloids are biosynthesized from amino acids via amines or aldehydes. This mechanism was established by BARTON, BATTERSBY, and SCOTT with tritium, carbon-13, and carbon-14 tracer experiments. The key reactions in biogenesis are Mannich-type condensation, aldol condensation, methylation with methionine, and oxidative coupling. In some cases, biogenetic theories have been fruitful guides in further structure determination (emetine and strychnine) and total synthesis (morphine). In this article, alkaloids are classified structurally, in the standard way, and one or two typical compounds in each group are briefly discussed in respect to chemistry and application.

2. Phenylalkylamines

Benzylamines and phenethylamines from natural sources are included in this chapter. Although ephedra alkaloids are also phenethylamine derivatives, they are discussed separately because of their characteristic pharmacological activities.

2.1. Simple Aromatic Amines

The *trans*-configuration of capsaicine (**1**), isolated from *Capsicum* species, was established by stereospecific synthesis [1]. Phenethylamines, such as dopamine (**2**) and tyramine (**3**), are important precursors of isoquinoline alkaloids and important neuroamines. Acanthoidine (**4**) and acanthoine (**5**) are found in *Carduus acanthoides.* The structure of the cactus alkaloid mescaline (**6**) was confirmed by synthesis from 3,4,5-trimethoxybenzoic acid [2].

Physical Properties.

Mescaline (**6**) [*54-04-6*], $C_{11}H_{17}NO_3$, M_r 211: *mp* 35 – 36 °C, *bp* 180 °C (at 1.6 kPa). Hydrochloride: *mp* 181 °C.

Pharmacological Properties. Mescaline (**6**) depresses the central nervous system of the frog and also mammals. The best-known action of this and the related cactus alkaloids is the production of color hallucinations. Acanthoidine (**4**) and acanthoine (**5**) exhibit some hypertensive activity.

Therapeutic Use: Experimental psychotomimetic.

2 R = OH Dopamine
3 R = H Tyramine

4 Acanthoidine

5 Acanthoine

6 Mescaline

2.2. Ephedra Alkaloids

Plants of genus *Ephedra* contain optically active alkaloids. Some are useful in medicine. The two major alkaloids, (−)-ephedrine (**7**) and (+)-pseudoephedrine (**8**), are diastereoisomers.

Physical Properties.

(−)-*Ephedrine* (**7**) [*299-42-3*], $C_{10}H_{15}NO$, M_r 165: *mp* 38.1 °C. Hydrochloride: *mp* 217 – 218 °C or 220 – 221 °C, $[\alpha]_D$ − 34 ° (wa-

ter). (±)-Form: *mp* 79 °C. Hydrochloride: *mp* 187 – 188 °C.

(+)-*Pseudoephedrine* (**8**) [*90-82-4*], $C_{10}H_{15}NO$, M_r 175: *mp* 119 °C, $[\alpha]_D^{20}$ +51 ° (ethanol). Hydrochloride: *mp* 181 – 182 °C, $[\alpha]_D^{20}$ +62 ° (water). (±)-Form: *mp* 118 °C.

7 Ephedrine

8 Pseudoephedrine

Preparation. (−)-Ephedrine can be obtained from the Ma Huang drug (*Ephedra "vulgaris", E. sinica* Stapf, *E. equisetina* Bunge) and other types of *Ephedra* [3]. The powdered drug is alkalized and extracted with benzene. The solution obtained is extracted with dilute acid, and the ephedrine crystallized after concentration of the aqueous phase.

Synthetic ephedrine continues to replace natural ephedrine.

Pharmacological Properties. Ephedrine (**7**) was originally employed as a mydriatic until the similar pharmacological action of adrenaline was observed. The mydriatic action of (−)-ephedrine is greater than that of (+)-ephedrine.

Therapeutic Use: Adrenergic (bronchodilator) [3].

Trade Names for (−)-*Ephedrine:* L-Sedrin (Lilly), Lexofedrin (Lexington). *Hydrochloride:* Darophedrin (Daro), Eggophedrin (Eggochemia), Ephedrin [Nagai] (Dainippon), Ensan Ephedrin (Meiji, Taisho), Ephedrin (Knoll), Ephetonin (Merck). *Sulfate:* Ectasule-Minus (Fleming), Ephedsol (Lannett), Iso-Phedrizem (Zemmer), Isofedrol (Blue Line). *Resinate:* Ephedrate (Upjohn), Ephedrol (Lilly), Ephedronal (Blue Line).

Trade Names for (+)-*Pseudoephedrine Hydrochloride:* Afrinol (Schering Corp.), Besan (Tutag), Eltor (Dow Chemical), First Sign (Williams), Novafed 120 (Dow Chemical), Sinufed (Hauck), Sudaped (Wellcome), Symptom 2 (Park Davis), Tussaphed (Knoll). *Sulfate:* Drixoral (Schering Corp.).

3. Pyrrolidine, Piperidine, and Pyridine Alkaloids

3.1. Pyrrolidine Alkaloids

Hygrine (**9**, racemic mixture) is a liquid tertiary aminoketone. The freshly isolated compound has a small negative optical rotation, but the free base racemizes rapidly. Cuscohygrine (**10**), isolated from the Peruvian *coca* shrub together with hygrine, is also oxidized to *N*-methylproline with chromic acid. The structure of shihunine (**11**), found in the Chinese plant *Dendrobium loliohense,* was determined by conversion into 1-methyl-2-phenylpyrrolidine [4].

9 Hygrine

10 Cuscohygrine

11 Shihunine

α-Kainic acid, isolated from the algae *Digenea simplex* [5] and *Centrocerus clavulatum* [6], has been shown to possess composition and configuration **14** on the basis of chemical [7] and X-ray evidence [8]. Kainic acid was enantioselectively synthesized from (*S*)-glutamic acid. Ene reaction of the 1,6-diene **12** produced the pyrrolidine **13**, which was converted into (−)-α-kainic acid [9].

(−)-Domoic acid (**19**) was found in the red algae *Chondria armata* [10]. The structure first proposed was revised by X-ray analysis and the total synthesis [11] of the optically active compound **19**. Diels-Alder reaction between the enone **15**, derived from (*S*)-glutamic acid, and diene **16** gave the bicyclic compound **17**, which was transformed into (−)-domoic acid (**19**) via the aldehyde **18**.

Physical Properties.

Hygrine (**9**) [*496-49-1*], $C_8H_{15}NO$, M_r 141: *bp* 76.5 °C (at 1.5 kPa), *bp* 81 °C (at 1.9 kPa). Picrate: *mp* 149 – 151 °C.

Cuscohygrine (**10**) [*454-14-8*], $C_{13}H_{24}N_2O$, M_r 224: *bp* 169 – 170 °C (at 3.1 kPa), *bp* 118 – 125 °C (at 0.3 kPa). Picrate: *mp* 216 – 217 °C (decomp.).

α-Kainic acid (**14**) [*487-79-6*], $C_{10}H_{15}NO_4$, M_r 213: *mp* 251 °C (decomp.), $[\alpha]_D^{24}$ – 14.8 ° (water).

Pharmacological Properties. Both kainic acid (**14**) and domoic acid (**19**) show potent neuronal excitatory activity.

α-Kainic acid is used therapeutically as an ascaricide.

Trade Names for α-Kainic Acid: Digenin (Takeda).

3.2. Piperidine Alkaloids

Some monocyclic piperidine alkaloids are classified according to the natural source into hemlock, areca, pomegranate, sedum, and lobelia alkaloids. Histrionicotoxins, the principal active ingredients of neotropical arrow poisons, have a spiro fused piperidine.

3.2.1. Hemlock Alkaloids

One of major components of hemlock, *Conium maculatum,* is coniine (**20**). The relative configuration of the other hemlock alkaloid, conhydrine (**21**), was assigned to the erythro form.

Physical Properties.

Coniine (**20**) [*458-88-8*], $C_8H_{17}N$, M_r 127: *bp* 166 °C, $[\alpha]_D^{19}$ + 16 ° (water).

Conhydrine (**21**) [*495-20-5*], $C_8H_{17}NO$, M_r 143: *mp* 121 °C, *bp* 226 °C, $[\alpha]_D$ + 10 ° (water).

Pharmacological Properties. Coniine (**20**) is highly toxic, inducing nausea and vomiting at an early stage and paralysis of the motor nerve endings followed by depression of the central nervous system.

3.2.2. Areca Alkaloids

Arecoline (**22**) [*63-75-2*], $C_8H_{13}NO_2$, M_r 155: *bp* 209 °C, *bp* 92 – 93 °C (at 0.9 kPa), is isolated from seeds of the betel nut palm *Areca catechu.* The compound is a powerful stimulant for the central nervous system and is used therapeutically as a cholinergic and anthelmintic.

22 Arecoline

3.2.3. Pomegranate Alkaloids

The root bark of the pomegranate, *Punica granatum,* contains several alkaloids. Pelletierine (**23**) was synthesized by acylation of α-picolyllithium with acetic anhydride followed by hydrogenation. Pelletierine racemizes on treatment with bases and for this reason is usually isolated as the racemate.

23 Pelletierine

Pelletierine (**23**) [*2858-66-4*], $C_8H_{15}NO$, M_r 141. Sulfate: *mp* 135 – 138 °C, $[\alpha]_D^{25}$ – 29.5 ° (water).

Pharmacological Properties. Pelletierine has been employed as an anthelmintic: It is highly toxic to tapeworms.

3.2.4. Lobelia Alkaloids

*Lobelia inflata,*commonly known as Indian tobacco, is an emetic herb rich in alkaloids. It is found in the Great Smoky Mountains. The main alkaloid, lobeline (**24**), was synthesized via a Mannich condensation of glutaraldehyde, methylamine, and benzoylacetic acid at pH 4.

24 Lobeline

Lobeline (**24**) [*90-69-7*], $C_{22}H_{27}NO_2$, M_r 337: *mp* 130 – 131 °C, $[\alpha]_D^{15}$ – 43 ° (ethanol). Hydrochloride: *mp* 178 – 180 °C, $[\alpha]_D^{20}$ – 43 ° (water).

Therapeutical Use: Respiratory stimulant.

3.2.5. Histrionicotoxins

Histrionicotoxin (**25**), isolated from *Dendrobates histrionicus,* contains the unique 1-azaspiro[5.5]undecane ring system. The structure and the stereochemistry at the C-2, C-6, C-7, and C-8 positions were elucidated by X-ray diffraction analysis of the hydrochloride [12].

25 Histrionicotoxin 283A

Pharmacological Properties. Histrionicotoxin (**25**) is a highly active venom and a mucosal-tissue irritant for mammals and reptiles. Both histrionicotoxin and its perhydroderivative selectively bind to the acetylcholine receptor and interrupt transsynaptic transmission of neuromuscular impulses [13]. Both compounds block postsynaptic membrane depolarization but do not interfere with acetylcholine binding. These toxins may prevent membrane depolarization by reversible bonding to the receptor ion channel or "ion conductance modulator" [13].

3.3. Pyridine Alkaloids

3.3.1. Tobacco Alkaloids

Tobacco alkaloids, include nicotine (**26**), nicotyrine (**27**), and anabasine (**28**). Nicotine is the principal alkaloid from tobacco plants (genus *Nicotiana*). Chromic acid oxidation gives nicotinic acid (**29**), whereas distillation from lime affords pyrrole and methylamine. Nicotyrine (**27**) is the corresponding tetradehydro compound, whereas anabasine (**28**) is an isomer of nicotine.

Physical Properties.

Nicotine (**26**) [*54-11-5*], $C_{10}H_{14}N_2$, M_r 162: *bp* 123 – 125 °C (at 2.3 kPa), $[\alpha]_D^{20}$ – 169 °. Hydrochloride: $[\alpha]_D^{20}$ + 104 ° (water).

26 Nicotine

27 Nicotyrine

28 Anabasine

29 Nicotinic acid

Nicotyrine (**27**) [*487-19-4*], $C_{10}H_{10}N_2$, M_r 158: *bp* 280–281 °C (at 99 kPa), *bp* 150–151 °C (at 2.1 kPa). Tartrate: *mp* 105–106 °C.

Anabasine (**28**) [*494-52-0*], $C_{10}H_{14}N_2$, M_r 162: *bp* 270–272 °C, *bp* 145–147 °C (at 1.9 kPa). Hydrochloride: $[\alpha]_D$ +16.5 ° (water).

Pharmacological Properties. LD_{50} in mice: 0.3 mg/kg i.v., 230 mg/kg orally for nicotine.

Nicotine (**26**) possesses the property of inducing an initial and transient stimulation, followed by depression, and finally paralysis of the autonomic ganglion.

Therapeutic Use: Ectoparasiticide. Nicotine has been used as an anthelmintic. Anabasine is used as an insecticide.

3.3.2. Theonelladin Alkaloids

Theonelladins A–D (**30**)–(**33**) were isolated from the Okinawan marine sponge *Theonella awinhoei*. Their structures were determined spectroscopically [14]. Theonelladin C (**32**) was isolated as a mixture with traces of anallogues having branched alkyl chains. These alkaloids exhibit potent antineoplastic activity against marine lymphomas L1210 cells (IC_{50} 4.7 µg/mL for A, 1.0 µg/mL for B, 3.6 µg/mL for C, 1.6 µg/mL for D) and human epidermoid carcinoma KB cells (IC_{50} 10 µg/mL for A, 3.6 µg/mL for B, 10 µg/mL for C, and 5.2 µg/mL for D) in vitro [14]. They also have powerful Ca^{2+}-releasing activity (twenty times more potent than caffein).

30 R = H Theonelladin A
31 R = CH_3 Theonelladin B

32 R = H Theonelladin C
33 R = CH_3 Theonelladin D

4. Tropane Alkaloids

About 50 alkaloids are known that have a tropane skeleton (**34**). All tropane alkaloids possess a hydroxy or acyloxy group at the C-3 position. They are found in the plants of Solanaceae, Convolvulaceae, Erythroxylaceae, and Rhizophoraceae. The most important source plants are *Atropa belladonna, Erythroxylum coca, Datura metel, D. stramonium, Scopola carniolica,* and *Hyoscyamus niger*.

34

4.1. Chemical and Physical Properties

Structure. The structures of important tropane alkaloids were determined by degradation methods about 100 years ago. The stereochemistries were worked out about 50 years ago. Both types of configurational isomers are known for the relative position of the nitrogen bridge and the substituent at C-3. For example, (−)-hyoscyamine (**35**) is *trans*, whereas tropacocaine (**37**) is *cis*.

The *cis* conformation was determined by acyl migration: Heating *N*-acetylnorpseudotropine hydrochloride (**38**) at 160 °C gave quantitatively *O*-acetylnorpseudotropine hydrochloride (**40**) via the cyclic intermediate **39**. On the other hand, no migration occurs with the α-hydroxyl compounds.

35 (−)-Hyoscyamine
(±)-form: Atropine

36 R = H Pseudotropine
37 R = COC_6H_5 Tropacocaine

The acyl part of (−)-hyoscyamine (**35**) is (−)-tropic acid, which easily undergoes racemization. Acidic or basic treatment of (−)-hyoscyamine affords the racemate, atropine.

38 **39** **40**

Cocaine (**42**) belongs to the β-series and carries a methoxycarbonyl group at the C-2 position. The absolute configuration was determined by the correlation with L-glutamic acid. Ecgonine (**41**) is the corresponding hydroxy acid.

41 $R^1 = R^2 = H$ Ecgonine**42** $R^1 = CH_3$; $R^2 = COC_6H_5$ Cocaine

The tropane alkaloid (−)-hyoscine (**43**) has an oxygen group on the pyrrolidine ring. Its racemate is the important alkaloid scopolamine. This alkaloid was converted by either acidic or alkaline hydrolysis into oscine (**45**) via scopine (**44**). The tetrahydrofuran ring formation was interpreted as a backside nucleophilic attack of the hydroxy oxygen upon either bridgehead of the epoxide ring, i.e., the C-6 or the C-7 position.

Physical Properties.

Atropine (Hyoscyamine) (**35**) [*51-55-8*], $C_{17}H_{23}NO_3$, M_r 289. (±)-Form: *mp* 114–116 °C. (−)-Form: *mp* 108.5 °C, $[\alpha]_D^{20}$ −21.0° (ethanol). Hydrobromide of the (−)-form: *mp* 152 °C.

43 (−)-Hyoscine
(±)-form: Scopolamine

44 Scopine

45 Oscine

Tropine (**47**) [*120-29-6*], $C_8H_{15}NO$, M_r 141: *mp* 63 °C, *bp* 233 °C.

Pseudotropine (**36**) [*135-97-7*], $C_8H_{15}NO$, M_r 141: *mp* 109 °C, *bp* 241 °C. Hydrochloride: *mp* 282 °C (decomp.).

Cocaine (**42**) [*50-36-2*], $C_{17}H_{21}NO_4$, M_r 303: *mp* 98 °C, *bp* 187–188 °C (at 0.01 kPa), $[\alpha]_D^{18}$ −35° (50 % ethanol), $[\alpha]_D^{20}$ −16° (chloroform). Hydrochloride [*53-21-4*]: *mp* 195 °C, $[\alpha]_D$ −72° (water). Nitrate [*5913-62-2*]: *mp* 58–63 °C. Sulfate [*5913-65-5*].

Ecgonine (**41**) [*481-37-8*], $C_9H_{15}NO_3$, M_r 185: *mp* 198 °C, $[\alpha]_D^{15}$ −45° (water). Hydrochloride: *mp* 246 °C: $[\alpha]_D^{15}$ −59° (water).

Hyoscine (**43**) (±)-form: Scopolamine [*51-34-3*], $C_{17}H_{21}NO_4$, M_r 303: $[\alpha]_D^{20}$ −28° (water). Hydrobromide [*114-49-8*]: *mp* 195 °C, $[\alpha]_D^{25}$ −24 to −26° (water).

4.2. Preparation

Synthesis. An effective synthesis of tropane alkaloids was developed by Robinson and Schöpf. Tropinone (**46**) was obtained in one step by the reaction of succinic aldehyde, methylamine, and acetonedicarboxylic acid [15]. Catalytic hydrogenation of **46** gave tropine (**47**). Tropine and its derivatives can be prepared commercially by this method. If this reaction is carried out with monomethyl acetonedicarboxylate, the ecgonine derivatives can be synthesized.

46 Tropinone **47** Tropine

Commercial Production. The procedure to extract tropane alkaloids from Solanaceae plants, e.g., the deadly nightshade, is as follows: The dried and finely divided materials are extracted with ethanol. Evaporation of the extract gives a residue, which is further extracted with water and then with 0.5 % sulfuric acid. The aqueous extracts are washed with ether or chloroform and then made basic by addition of ammonia under cooling. The alkaloids are extracted with ether and then with chloroform. Evaporation of the solvents gives the alkaloidal fractions, which are then converted to salts and purified by recrystallization.

Cocaine (**42**) is produced industrially from natural sources. The alkaloid is extracted from coca leaves with dilute sulfuric acid and hydrolyzed to ecgonine (**41**). The purified base is esterified with methanol and then acylated with benzoyl chloride to cocaine.

4.3. Pharmacological Properties

Atropine first stimulates but eventually depresses the central nervous system, causing hallucinations, delirium, and convulsions, and finally coma. Scopolamine has anticholinergic activity. Cocaine (**42**) is a potent anaesthetic, mydriatic, and sedative.

Therapeutic Use.

Atropine is used as an anticholinergic. It is employed principally in medicine as a mydriatic, to dilate the pupil of the eye. It also is used when paralysis of parasympathetic nervous activity is desired, e.g., to suppress branchial or intestinal spasms.

Cocaine is used as a topical anesthetic and a central nervous system stimulant.

Ecgonine is a topical anesthetic, and *scopolamine* is a anticholinergic. The last has been used also as a sedative, a preanesthetic, and to control motion sickness.

Trade Names.

Atropine: Atropinol (Dr. Winzer). *Sulfate:* Atropen (Survival Tech.), Atropine Dispersa (Dispersa), Atropisol (Cooper Vision), Atrop (Sigma), Eyesule (Duncan Flockhart), Isopto-Atropin (Alcon), Liotropina (Sifi), Ocu-Atro (Orion), Oftan-atropin (Star), Skiatropin (Chauvin-Blache), Atratan (Mallinckrodt), Tropintran (Kwizda), Ryusan Atropine (Santen, Iwaki, Torii, Takeda, Tanabe), Opulets Atropine (Alcon), AtropinPOS (Ursapharm), Atropin sulfat (Hameln), Atropin Drobena (Drobena), Atropin Sulfuric Thilo (Thilo), Atropin Sufuric (Cascan), Minims Atropine (S. N. P.). *Methionitrate:* Eumycrin (Winthrop).

Cocaine: Psicaine (Merck), Delcaine (Roquies), Ensan Cocaine (Sankyo, Takeda, Shionogi, Dainippon).

Scopolamine Borate: Boro-Scopol (Winzer). *Hydrobromide:* Isopto Hyoscine (Alcon), Scopolamine Dispersa (Dispersa), Scops (Spret-Mauchant), Triptone (Commerce Drug), Minims Hyoscine (S. N. P.), Hisco (Kyorin). *Butyl bromide:* Buscopan (Boehringer Ingelheim).

5. Pyrrolizidine Alkaloids

Occurrence and Preparation. A number of pyrrolizidine alkaloids are isolated from *Senecio* plants, the largest genus of the Compositae. Generally hydrolysis of the alkaloids gives necine bases and necic acids. Thus retronecine (**48**) was obtained by the hydrolysis of echimidine (**56**), monocrotaline (**57**), crobarbatine (**58**), and indicine *N*-oxide (**59**). Heliotridine (**49**) is formed from heliotrine (**55**). Alkaloids **48** and **49** are stereoisomers at the C-7 position. All four possible stereoisomers, hastanecine (**50**) [16], dihydroxyheliotridane (**51**) [16], platynecine (**52**), and turneforcidine (**53**), are obtained by degradation of parent alkaloids or as natural products. The structures were established by careful spectroscopical analysis. They can be synthesized by many methods [16–23].

Trachelanthamidine (**54**) [18] was synthesized based on the presumed biosynthetic pathway [19]: The dialdehyde **60** was allowed to stand for several days at pH 7 to give **61**. Sodium borohydride reduction gave racemic trachelanthamidine. Asymmetric synthesis was also attempted [20].

(±)-Retronecine (**48**) and (±)-turneforcidine (**53**) were synthesized via sulfenocycloamination ring closure. Regio- and stereoselective [3.3] sigmatropic rearrangement between the 3-pyrrolidinone **62** and the *cis*-butenediol derivative **63** gave the ketone **64**, which was then transformed into the amine **65**. Treatment of the amine **65** hydrochloride with phenylsulfenyl chloride and base-induced ring closure produced the pyrrolizidine (**66**), which was converted into (±)-retronecine (**48**) and (±)-turneforcidine (**53**) in few steps [23].

Alexine (**67**) [*116174-63-1*], $C_8H_{15}NO_4$, M_r 189: *mp* 162 – 163 °C, $[\alpha]_D^{20}$ +40 ° (water), was isolated from the pods of *Alexa leiopetala* (Leguminoceae) and its structure was elucidated on the basis of spectroscopic evidence (MS, ^{1}H and ^{13}C NMR). A total synthesis of **67** starting from D-glucose has been reported [25].

48 Retronecine **49** Heliotridine **50** Hastanecine

51 Dihydroxyheliotridane

52 Platynecine

53 Turneforcidine

54 Trachelanthamidine

55 Heliotrine

56 Echimidine

57 Monocrotaline

58 Crobarbatine

59 Indicine *N*-oxide

Pharmacological Properties. The pyrrolizidine alkaloids exhibit selective toxic action on the liver. This toxicity is associated with the metabolic conversion of the pyrrolizidine nucleus to a pyrrole [24]. *Indicine N-oxide* has proved to be highly active against transplanted neoplasms, Walker-256 carcinosarcoma, melanoma B-16, leukaemia L-1210, leukaemia P-388, and leukaemia P-1534 in mice and rats, inhibiting up to 91 percent of transplanted growth. *Alexine* is weak inhibitor of glucosidase activity [26].

6. Indolizidine Alkaloids

6.1. Ipomoea Alkaloids

Ipalbine (**68**), which is the *O*-β-D-glucoside of ipalbidine (**69**), occurs in *Ipomoea alba.* It is dextrorotatory, $[\alpha]_D^{23}$ +32.5° (ethanol). The structure was confirmed by the total synthesis from 2-methoxypyrroline and methyl acetoacetate [27]. The seeds of *Ipomoea muricata*, a plant grown in Senegal, affords ipomine (**70**) and ipalbidine (**69**). Acid hydrolysis of ipomine gives ipalbidine, D-glucose, and *p*-coumaric acid, whereas enzymatic hydrolysis with emulsin yields ipalbidine (**69**) [28].

69 Ipalbidine

70 Ipomine

6.2. Thylophora Alkaloids

Septicine (**71**) and thylophorine (**72**), both isolated from *Ficus septica,* have been synthesized by a number of groups [29–35]. Both are synthesized through 1,3-dipolar cycloaddition [35].

71 Septicine

72 Tylophorine

Pharmacological Properties. Thylophorine (**72**) and its positional isomers showed antitumor activity.

6.3. Elaeocarpus Alkaloids

The structure of elaeocarpine (**73**) was determined by X-ray analysis of its hydrobromide [36]. Racemates of elaeokanine A (**74**) and elaeokanine C (**75**) have been synthesized by a nitrone 1,3-dipolar cycloaddition [37], a versatile method for synthesis of elaeokanine alkaloids [38].

73 Elaeocarpine

74 Elaeokanine A

75 Elaeokanine C

6.4. Dendrobatid Alkaloids

Pumiliotoxins A (**76**) and B (**77**) and gephyrotoxin (**78**) were isolated from skin extracts of frogs belonging to the Dendrobatid family [12]. Pumiliotoxins A and B have in common the unusual 6-alkylideneindolizidine (1-azabicyclo[4.3.0]nonane) ring system. They differ only in the side chain. Overman synthesized the dendrobatid toxin 251 D (**79**), which had been isolated from *Dendrobates tricolor*, via iminium-ion vinylsilane cyclization [39].

Structure of gephyrotoxin (**78**) was established by X-ray crystallographic analysis of its *p*-bromobenzoate [40]. Total synthesis of gephyrotoxin was accomplished by Kishi and Hart [41–43]. The stereoselectivity of the Kishi synthesis was controlled through hydrogenation reactions. On the other hand, Hart controlled the stereochemistry on cyclization of carbinolamide with formic acid.

Pharmacological Properties. Pumiliotoxin B (**77**) shows powerful cardiotonic and myotonic activity, which is believed to involve calcium-dependent mechanisms [44].

78 Gephyrotoxin

76 Pumiliotoxin A

77 Pumiliotoxin B

79 Toxin 251 D

6.5. Miscellaneous

Certain legume forages used for cattle feed have been known to produce excessive salivation when infested by *Rhizoctonia leguminicola.* This was shown to be caused by the presence of *slaframine* (**80**) [45]. The structure and absolute stereochemistry were established by Rine-

HART [46]. Slaframine has been synthesized by three groups [47–49]. Dieckmann cyclization was used to construct the indolizidine skeleton in the first two syntheses [47], [48], whereas the key step of the other synthesis was the intramolecular Diels-Alder reaction [49].

80 Slaframine

Slaframine itself is not bioactive but is oxidized in vivo to a compound that can interact with muscarinic acetylcholine receptors, producing the observed symptoms [50].

Castanospermine (**81**) [*79831-76-8*], $C_8H_{15}NO_4$, M_r 175: *mp* 212 – 215 °C (ethanol), $[\alpha]_D^{25}$ + 79.7° (water), was isolated from the toxic seeds of the Australian legume *Castanospermum australe* and its structure was determined by spectroscopic considerations [51]. The first total synthesis of (+)-castanospermine starting from D-glucose was reported by GANEM [52]. Since castanospermine shows inhibitory activity against tumors and HIV, extensive synthetic studies have been performed. Synthesis of **81** and related alkaloids is reviewed in [53]. More recently **81** has been prepared from methyl α-D-glucopyranoside [54].

81 Castanospermine

7. Quinolizidine Alkaloids

The quinolizidine ring system is a common structural unit in many alkaloids. Lupinine and related alkaloids and the Lythraceae alkaloids are discussed in this section.

7.1. Lupinine and Related Alkaloids

Occurrence and Synthesis. Bicyclic, tricyclic, and tetracyclic compounds are found in a large family of the *Leguminosae.* Representative compounds are lupinine (**82**), cytisine (**84**), and sparteine (**85**). Matrine (**86**) represents another type of tetracyclic lupine alkaloids.

82 R^1 = H, R^2 = CH_2OH Lupinine
83 R^1 = CH_2OH, R^2 = H Epilupinine

84 Cytisine

85 Sparteine

86 Matrine

Lupinine (**82**), isolated from yellow lupine seed, is the simplest member of the family. A synthesis along lines of the presumed biosynthesis was carried out by VAN TAMELEN [55].

Lupinine (**82**) is the less stable isomer. Its axial hydroxymethyl group is hydrogen-bonded to the nitrogen atom.

Sparteine (**85**) has four asymmetric centers, two of them interdependent because of the bridge. There should be three pairs of enantiomers, and in fact three different diastereoisomers have been isolated from the plants *Cytisus ratisbonensis, C. scoparius, Lupinus barbiger, L. laxus, L. luteum, L. niger, Retama sphaerocarpa, Sarothamnus scoparius, Spartium junceum,* and *S. scoparium.* 8-Oxo-α-isosparteine (**89**) was synthesized very simply by condensation of the racemic or *meso* forms of anaferine (**87**) with formaldehyde. The intermediate products are the spiranoid ketals **88**, which were converted on treatment with acetic anhydride into **89** [56].

87 → **88** → **89**

Matrine (**86**) occurs in many species of *Sophora.* Most of the structural features were recognized through degradation experiments. The straightforward synthesis starts from the Schiff base **90** of the ethyl ester of β-alanine and ethyl β-ketopimelate. Hydrogenation of **90** affords **91**, which is converted by Dieckmann condensation and hydrolysis to **92**. Monocyanoethylation by the enamine method gives **93**, and hydrogenation provides ($\pm$)-matrine (**86**).

Physical Properties.

Lupinine (**82**) [*486-70-4*], $C_{10}H_{19}NO$, M_r 169: *mp* 68.5 – 69.2 °C, *bp* 160 – 164 °C (at 0.5 kPa), *bp* 269 – 270 °C (at 100.6 kPa), $[\alpha]_D^{28}$ $-21°$ (ethanol). Hydrochloride: *mp* 208 – 213 °C, $[\alpha]_D$ $-14°$ (water).

Cytisine (**84**) [*485-35-8*], $C_{11}H_{14}N_2O$, M_r 190: *mp* 152 – 153 °C, *bp* 218 °C (at 0.3 kPa), $[\alpha]_D^{17}$ $-120°$ (water).

Matrine (**86**) [*519-02-8*], $C_{15}H_{24}N_2O$, M_r 248: *mp* 87 °C, $[\alpha]_D^{20}$ $+38°$ (ethanol). Picrate: *mp* 167 – 169 °C.

Sparteine (**85**) [*90-39-1*], $C_{15}H_{26}N_2$, M_r 234: *bp* 173 °C (at 1.1 kPa), $[\alpha]_D^{21}$ $-16.4°$ (ethanol).

Pharmacological Properties. Sparteine (**85**) has little effect on the central nervous system but paralyzes the motor nerve terminations and the sympathetic ganglia. It depresses circulation.

Therapeutic Use of Sparteine: Oxytocic.

Trade Names for Sparteine: Spartopan (Paillusseau). *Sulfate:* Actospar (Sandoz), Depasan (Giulini), Spartocin (Ayerst, Benton), Tocosamine sulfate (Trent). *Theophyllinate:* Spartofillina (Amelix, Terapeutico M. R.), Uterospan (Nihonzoki).

7.2. Lythraceae Alkaloids

Occurrence and Synthesis. Macrocyclic quinolizidine alkaloids, isolated from members of the *Lythraceae,* can be classified into three structural types. These are represented by the biphenyllactone cryogenine (**94**), the diphenyl ether lactone vertaline (**95**) [57–59], and the carbocyclic biphenyl lythrumine (**97**). Several total syntheses of lactonic lythraceae alkaloids have been reported, most using Mannich reactions of pelletierine with substituted benzaldehydes, biaryls, or diaryl ethers to assemble the quinolizidine moiety.

Vertaline (**95**) and decaline (**96**) were synthesized via [3 + 2] cycloaddition [59].

Pharmacological Properties. Some lythraceae alkaloids increase blood glucose level and lower mean blood pressure; they show sedative activity in dogs and guinea pigs.

97 Lythrumine

8. Quinoline, Quinazoline, and Acridone Alkaloids

8.1. Quinoline Alkaloids

Occurrence and Synthesis. Most quinoline alkaloids are derived from anthranilic acid. Dictamnine (**98**) is a representative of furoquinoline alkaloids. Ribalinidine (**99**), which has the dihydropyranoquinoline structure, is isolated as the L-form. Bucharamine (**100**), spectabiline (**103**), and balfourodine (**104**) contain the dihydrofuroquinoline ring system. Ravenine (**101**) and ravenoline (**102**) possess 1,1-dimethylallyl and 1,2-dimethylallyl moieties, respectively.

101 Ravenine

102 Ravenoline

103 Spectabiline

104 Balfourodine

Pumiliotoxin C (**105**) was originally isolated from the skin of the neotropical frogs *Dendrobates pumilio* and *D. auratus* [40], [60]. This alkaloid has been synthesized by several groups [61], [62]. YAMAMOTO developed a practical synthesis. The enone **106**, prepared via the Stobbe condensation of 2-methylcyclohexanone, was converted to the *cis*-fused hexahydroindanone **107** by stereoselective hydrogenation and elaborated via alkylaluminum-promoted Beckmann rearrangement of the oxime tosylate **108** to (±)-pumiliotoxin C (**105**) [63].

105 Pumiliotoxin C

Physical Properties. *Dictamnine* (**98**) [*484-29-7*], $C_{12}H_9NO_2$, M_r 199: *mp* 133 °C. Hydrochloride: *mp* 170 °C (decomp.). Picrate: *mp* 163 °C.

8.2. Quinazoline Alkaloids

Occurrence and Synthesis. A number of quinazoline alkaloids are isolated from the *Rutaceae* plants. Anthranilic acid is thought to be the precursor in the biogenesis. Vasicine (**109**), isolated from *Adhatoda vasica* and *Pegunum harmala,* can be oxidized with $KMnO_4$ to give 4-quinazolone. Arborine (**110**), glycosminine (**111**), glomerine (**112**), crysogine (**113**), rutecarpine (**114**), euxylophoricines A (**115**) and C (**116**), and evodiamine (**117**) were synthesized in a one-pot reaction by iminoketene cycloaddition [64], [65]. Treatment of the sulfinamide anhydrides **120** and **121**, derived from anthranilic acid (**118**) or *N*-methylanthranilic acid (**119**), with imines or primary or secondary amides gives the quinazolone derivatives **123**. The iminoketenes **122** were postulated as the intermediates.

Physical Properties.

Vasicine (**109**) [*6159-55-3*], $C_{11}H_{12}N_2O$, M_r 188. (±)-Form: *mp* 210 °C (from ethanol). (−)-Form: *mp* 212 °C, $[\alpha]_D^{14}$ −254° (*c* = 2.4 in chloroform) or −62° (*c* = 2.4 in ethanol). Hydrochloride: *mp* 208 °C.

Rutecarpine (**114**) [*84-26-4*], $C_{18}H_{13}N_3O$, M_r 287: *mp* 259.5 – 260 °C.

Evodiamine (**117**) [*518-17-2*], $C_{19}H_{17}N_3O$, M_r 303: *mp* 278 °C, $[\alpha]_D^{15}$ +352° (acetone), $[\alpha]_D$ +440° (chloroform).

Pharmacological Properties. Vasicine (**109**) is an active bronchodilator. On injection rutecarpine (**114**) increases arterial pressure.

8.3. Acridone Alkaloids

Acridone alkaloids are also derived biogenetically from anthranilic acid. It was reported that certain bases of this class possess antitumor properties. Acronycine (**125**) was synthesized from the acridone derivative **124** [66].

9. Isoquinoline Alkaloids

The isoquinoline alkaloids comprise a large number of naturally occurring compounds of varying complexity [67–69]. They are classified as follows:

1) simple isoquinoline alkaloids
2) phenylisoquinoline alkaloids
3) 1-benzylisoquinoline alkaloids
4) 2-benzylisoquinoline alkaloids
5) pavine and isopavine alkaloids
6) bisbenzylisoquinoline alkaloids
7) cularine and related alkaloids
8) proaporphine alkaloids
9) aporphine alkaloids
10) protoberberine alkaloids
11) protopine alkaloids
12) phthalide alkaloids
13) ochotensine and related alkaloids
14) rheadan alkaloids
15) morphine and related alkaloids
16) hasubanan alkaloids
17) emetine and related alkaloids
18) erythrina alkaloids
19) cephalotaxine alkaloids
20) protostephanine alkaloids
21) benzophenanthridine alkaloids
22) dibenzopyrrocoline alkaloids
23) phenethylisoquinoline alkaloids

Furthermore, some isoquinoline derivatives have been found in bacteria. The 1-

benzylisoquinoline alkaloids, derived biogenetically from tyrosine or phenylalanine, are transformed to a number of the above isoquinoline alkaloids by phenol oxidation [70] or modification in the presence of some plant enzymes [71], [72].

9.1. Simple Isoquinoline Alkaloids

Occurrence and Synthesis. The simple isoquinoline alkaloids, such as salsoline (**126**), anhalamine (**127**), corypalline (**128**), thalifoline (**129**), and pilocereine (**130**), are tetrahydroisoquinolines substituted in the C-1 position by methyl, hydrogen, oxygen, or isobutyl groups. The stereochemistry of the optically active alkaloids is determined by conversion to an amino acid of known configuration. Optical rotatory dispersion (ORD) and circular dichroism (CD) spectra are useful for determination of absolute configuration. The isoquinoline moiety is usually obtained by the Bischler-Napieralski reaction [73], the Pictet-Spengler reaction [74], which mimics physiological reaction conditions, or the Pomeranz-Fritsch reaction [75] and its modification [76]. All of these classical methods for forming the isoquinoline ring have been employed for the synthesis of the simple isoquinoline alkaloids and some of the alkylisoquinoline alkaloids.

Pilocereine (**130**), isolated from *Lophocereus schottii,* is the only example of a phenolic oxidation product in simple isoquinoline alkaloids. Tracer experiments showed that the phenolic oxidation of lophocerine (**131**, racemic mixture) by enzymes in the plant furnishes pilocereine (**130**) [77], [78]. This coupling process was reproduced in the laboratory by potassium ferricyanide oxidation of **131** at pH 6 [79].

Physical Properties.

Salsoline (**126**) [*89-31-6*], $C_{11}H_{15}NO_2$, M_r 193: *mp* 221 °C, $[\alpha]_D^{20}$ +34.5° (0.1 M hydrochloric acid). Hydrochloride: *mp* 174 – 175 °C, $[\alpha]_D$ +31.0° (methanol).

Anhalamine (**127**) [*643-60-7*], $C_{11}H_{15}NO_3$, M_r 209: *mp* 189 – 191 °C. Hydrochloride: *mp* 258 °C.

Pilocereine (**130**) [*2552-47-8*], $C_{45}H_{65}N_3O_6$, M_r 744: *mp* 176.5 – 177 °C. Methyl ether: *mp* 103 – 105 °C, solidifies and remelts at 153 – 155 °C.

Pharmacological Properties. Salsoline (**126**) shows an antihypertensive activity.

Therapeutic Use of Salsoline: Antihypertensive.

130 Pilocereine

131 Lophocerine

9.2. Phenylisoquinoline Alkaloids

The unique structure of rufescine (**132**), isolated from *Abuta imene* and *A. rulesceus,* was determined by spectroscopic methods and confirmed by synthesis [80].

The structure of the optically active cryptostyline I (**133**) was derived from NMR, UV, and mass spectra. Final confirmation for the structure, as well as the determination of the absolute configuration, was obtained by X-ray analysis [81]. Cryptostyline II (**134**) and III (**135**) were synthesized via the Bischler-Napieralski reaction [81].

132 Rufescine

133 Cryptostyline I

134 Cryptostyline II

135 Cryptostyline III

9.3. 1-Benzylisoquinoline Alkaloids

Structure, Occurrence, and Synthesis. The structures of the simple 1-benzylisoquinolines and the biogenetically related alkaloids were established by classical methods involving Hofmann degradation and oxidation; the phenolic functions were usually protected by O-ethylation.

The absolute configuration of this class of alkaloids was initially established by Corrodi and Hardegger [82], who ozonized (−)-*N*-norlaudanosoline (**137**) to give the known *N*-carboxyethyl-l-aspartic acid. The stereochemistry of related alkaloids was then determined by comparison with **137** or its derivatives.

The structures of the newer benzylisoquinolines have been determined by physical methods, including mass spectra [83], ^{1}H NMR, ^{13}C NMR, and UV. Further, the chirality of the alkaloids was established by optical rotatory dispersion [84], [85] and circular dichroism [86], where the *S*-series of 1-benzylisoquinolines show positive Cotton effects in the 280 – 240 nm region.

Papaverine (**136**), norlaudanosoline (**137**), coclaurine (**138**), reticuline (**139**), and laudanosine (**140**) are 6,7-dioxygenated isoquinoline derivatives, whereas petaline (**141**) possesses the 7,8-dioxygenated isoquinoline structure. Aobamine (**142**), isolated from *Corydalis ochotensis var. raddeana* [87], has a formyl group and must be derived from protoberberine alkaloids.

140 R = CH_3 (+)-Laudanosine

141 Petaline

142 Aobamine

The simple benzylisoquinoline alkaloids have mostly been synthesized via the Bischler-Napieralski reaction. Although the phenolic hydroxyl group is usually protected as the benzyl

ether during synthesis, the phenolic function in amides need not be protected in the Bischler-Napieralski reaction [88].

Simple 1-benzylisoquinolines have also been prepared from isoquinolines devoid of a substituent in the 1-position by application of the Grignard reaction [89], the Reissert reaction [90], or the Stevens rearrangement [91], [92].

Papaverine (**136**) was synthesized via the Bischler-Napieralski reaction as follows: the Schotten-Baumann reaction between the phenethylamine **143** and the acyl chloride **144** gave the amide **145**. Cyclization with phosphorous pentoxide afforded the 3,4-dihydroisoquinoline **146**. Mild dehydrogenation of **146** gave papaverine [93].

The Pictet-Gams modification was also used for the synthesis of papaverine [94].

Reticuline (**139**) is an important precursor of protoberberine, morphine, aporphine, spirobenzylisoquinoline, and rheadan alkaloids [95].

Physical Properties.

Papaverine (**136**) [*58-74-2*], $C_{20}H_{21}NO_4$, M_r 339: *mp* 147 °C. Hydrochloride [*61-25-6*]: *mp* 220 – 225 °C.

Coclaurine (**138**) [*486-39-5*], $C_{17}H_{19}NO_3$, M_r 285: *mp* 220 – 221 °C. Hydrochloride: *mp* 263 – 264 °C.

Reticuline (**139**) [*485-19-8*], $C_{19}H_{23}NO_4$, M_r 329. (±)-Form: *mp* 146 °C. Picrate. (±)-Form: *mp* 188 – 190 °C. Perchlorate. (+)-Form: *mp* 203 – 204 °C, $[\alpha]_D^{18}$ + 88.3 ° (ethanol).

Laudanosine (**140**) [*2688-77-9*], $C_{21}H_{27}NO_4$, M_r 357. (±-Form): *mp* 114 – 115.5 °C. (+)-Form: *mp* 89 °C, $[\alpha]_D^{16}$ + 106 ° (97 % ethanol), $[\alpha]_D^{16}$ + 130 ° (chloroform).

Pharmacological Properties. Small doses of papaverine (**136**) produce a light sleep that does not become deeper as the dose is increased because reflex irritability and some stimulating action is brought about. There is a tendency for the heart to slow, an effect more pronounced than with morphine or codeine.

Therapeutic Use of Papaverine: Smooth muscle relaxant and cerebral vasodilator.

Trade Names for Papaverine Chloride: Artegodan (Artesan), Dipav (Lemmon), Pameion (Simes), Panergon (Mack), Pavabid (Marion), Pavakey (Key), Paveron (Luar, Karlspharma), Therapav (Coopar, Berlex), Vasal (Tutag), Ensan Papaverin (Iwaki, Nakakita, Torii). *Papaverine Sulfate:* Copavin (Lilly), Maspaver (Juste).

9.4. 2-Benzylisoquinoline Alkaloids

The structure of sendaverine (**147**), a 2-benzylisoquinoline isolated from *Corydalis aurea* and present in the alkaloid mixture corpaverine [96], [97], was largely determined by IR, UV, NMR, and mass spectra [98]. The related alkaloid corgoine (**148**) was obtained from *Corydalis gortshakovii* [99].

147 R = CH_3 Sendaverine **148** R = H Corgoine

Sendaverine (**147**) was synthesized by utilizing the Bischler-Napieralski or the Pictet-Spengler reaction [98]. Sendaverine (**147**) was also synthesized via isochroman-3-ones prepared by thermolysis of benzocyclobutenes [100].

9.5. Pavine and Isopavine Alkaloids

The pavine alkaloids, represented by argemonine (**149**), are characterized by a cyclooctane ring system. The structure of **149** was determined from spectral data and confirmed by comparison with the synthetic sample obtained from

papaverine by reduction with tin and hydrochloric acid [101]. The absolute configuration was established by correlation with L-aspartic acid as well as by optical rotatory dispersion [102].

149 Argemonine

150 Reframidine

The isopavine alkaloid reframidine (**150**) was obtained via the aziridinium salt [103]. The syntheses of several isopavine alkaloids have been reported by DYKE [104] and UMEZAWA [105].

9.6. Bisbenzylisoquinoline Alkaloids

Structure and Synthesis. Bisbenzylisoquinoline alkaloids are classified by the bonding position of the ether. Dauricine (**151**) is a tail-tail mono ether, liensinine (**152**) is a head-tail mono ether, and oxyacanthine (**153**) is a head-head and tail-tail bis ether. Berbamine (**154**) is a different type of head-head and tail-tail bis ether. Trilobine (**155**) has a head-head and tail-tail tri ether structure, and tubocurarine (**156**) is a head-tail bis ether. Thalicarpine (**157**) and pakistanamine (**158**) have aporphine and proaporphine moieties, respectively.

151 Dauricine

152 Liensinine

153 Oxyacanthine

154 Berbamine

155 (+)-Trilobine

156 Tubocurarine

157 Thalicarpine

158 (+)-Pakistanamine

Classical degradative methods were used to determine the structures of the bisbenzylisoquinoline alkaloides. In addition, the fragmentation pattern obtained by mass spectroscopy has proved useful in "typing" the bisbenzylisoquinoline alkaloids, while their NMR spectra have been employed not only to locate the position of the methoxy group but also to narrow the stereochemical possibilities. NMR examination has shown that the chemical shifts of the aromatic methoxy group (due to the proximity of the ring system) can aid in identifying the type of oxygen bridge. The absolute configuration of the bisbenzylisoquinolines was readily determined from the chirality of products obtained by cleavage with sodium in liquid ammonia or by measurement of the optical rotatory dispersion (ORD) [106], [107].

Synthesis of bisbenzylisoquinoline alkaloids is well reviewed by SHAMMA and GEOGRIEV [108].

Bisbenzylisoquinoline alkaloids have been prepared from simple 1-benzylisoquinoline precursors by classical methods involving a combination of the Bischler-Napieralski and Ullmann reaction [109–112] or by the oxidative coupling of appropriately substituted phenolic substrates [113]. Presently the most promising avenue to the bisbenzylisoquinolines appears to be via an improved Ullmann diaryl ether synthesis which uses pentafluorophenyl copper in dry pyridine [114].

Physical Properties.

Dauricine (**151**) [*524-17-4*], $C_{38}H_{44}N_2O_6$, M_r 624: *mp* 115 °C, $[\alpha]_D^{11}$ − 139 ° (methanol). Dimethiodide: *mp* 204 °C, $[\alpha]_D^{26}$ − 114 ° (water).

Oxyacanthine (**153**) [*548-40-3*], $C_{37}H_{40}N_2O_6$, M_r 608: *mp* 216 – 217 °C, $[\alpha]_D^{20}$ + 131.5 ° (chloroform). Dihydrochloride: *mp* 270 – 271 °C, $[\alpha]_D$ + 185.5 ° (water).

Berbamine (**154**) [*478-61-5*], $C_{37}H_{40}N_2O_6$, M_r 608: *mp* 197 – 210 °C, $[\alpha]_D^{20}$ + 114.6 ° (chloroform). Hydrochloride: $[\alpha]_D^{20}$ + 63.2 ° (water). Dihydrochloride: *mp* 270 °C (decomp.).

Trilobine (**155**) [*6138-73-4*], $C_{35}H_{34}N_2O_5$, M_r 562: *mp* 237 °C, $[\alpha]_D$ + 307 ° (chloroform). *N*-methyl derivative: *mp* 215 °C, $[\alpha]_D$ + 317 ° (chloroform).

Tubocurarine chloride (**156**) [*57-94-3*], $C_{37}H_{42}N_2O_6Cl_2$, M_r 681. (+)-Form: *mp* 270 °C (decomp.), $[\alpha]_D^{22}$ + 190 ° (water), $[\alpha]_D^{23}$ + 219 ° (methanol). (−)-Form: *mp* 268 °C, $[\alpha]_D^{20}$ − 258 ° (water).

Thalicarpine (**157**) [*5373-42-2*], $C_{41}H_{48}N_2O_8$, M_r 696: *mp* 160 – 161 °C, $[\alpha]_D^{25}$ + 133 ° (methanol), $[\alpha]_D^{25}$ + 89 ° (chloroform).

Pharmacological Properties. KUPCHAN studied the structural requirements for tumor-inhibitory activity by bisbenzylisoquinoline alkaloids and related compounds. Only one linkage of the isoquinoline unit appears to be necessary, and activity is seemingly unaffected by the configuration of the asymmetric centers or whether the nitrogen is secondary or tertiary.

However, the presence of two methylimino groups destroys activity.

Therapeutic Use of Tubocurarine Chloride: The (+)-form is used as a skeletal muscle relaxant [115] and as a diagnostic aid (myasthenia gravis).

9.7. Cularine and Related Alkaloids

The cularine-type alkaloids are characterized by an oxepine ring and a 7,8-dioxygenated isoquinoline moiety. The gross structure of cularine (**159**) was assigned by systematic Hofmann degradation and reductive cleavage of the biphenyl ether linkage [116], and confirmed by X-ray crystallography [117], [118]. The structures of the related alkaloids were established by comparing the mass spectra with that of cularine (**159**). A new cularine alkaloid norsarcocapnine (**160**) was isolated from *Ceratocapnos heterocapra* and the structure was elucidated on the basis of spectroscopic evidence [119]. The structure of the complex alkaloid cancentrine (**161**) was established by X-ray analysis of a degradation product [120].

The cularine-type alkaloids are biosynthesized in plants by phenol oxidation of the 8-oxygenated benzylisoquinoline. Laboratory demonstration of this biosynthesis was attempted [121], [122]. Cularine and related alkaloids were prepared by the Pomeranz-Fritsch and related reactions [123] and by the Ullmann reaction [124]. A synthesis of (+)-cularine (**159**) was achieved via oxylium ions and diastereoselective reductive methylation [125].

9.8. Proaporphine Alkaloids

The representative proaporphine alkaloids are glaziovine (**162**), pronuciferine (**163**), orientalinone (**164**), and litsericine (**165**).

159 Cularine

160 (+)-Norsarcocapnine

161 Cancentrine

162 R = H (+)-Glaziovine
163 R = CH_3 (+)-Pronuciferine

164 (−)-Orientalinone

165 Litsericine

The proaporphine alkaloids possess a tetracyclic nucleus incorporating a cross-conjugated cyclohexadienone or related system. Even before they were isolated from nature, their existence was suggested by Barton [126] as biogenetic precursors converted by phenolic oxidation to the aporphines. Indeed, this mechanism has been used to determine the structures of the proaporphines.

The proaporphine alkaloids have been prepared by a variety of classical and biomimetic methods [127–131].

9.9. Aporphine Alkaloids

Structure and Synthesis. Isoboldine (**166**), glaucine (**167**), corytuberine (**168**), isothebaine (**169**), anonaine (**170**), and bulbocapnine (**171**) are typical aporphine alkaloids.

166 R = H Isoboldine
167 R = CH_3 Glaucine

168 Corytuberine

169 Isothebaine

170 Anonaine

171 Bulbocapnine

The structures of the aporphine alkaloids are characterized by a 9,10-dihydrophenanthrene system. Both classical methods and UV, NMR, and mass spectra have been effectively applied. The absolute configurations have been determined by relating the benzylisoquinoline laudanosine of known chirality to (−)-glaucine (**167**) [132] and by optical rotatory dispersion (ORD) [133], [134]. The marked ORD abnormalities are probably due to steric distortion of the biphenyl ring system [135].

The aporphine alkaloids have been synthesized by the Pschorr reaction [136], either from the accessible 1-(2-aminobenzyl)isoquinolines [137–139] or from the 8-aminoisoquinolines, which are difficult to synthesize [140]. Decomposition of the diazonium intermediates by photolysis instead of the usual thermolysis improved the yields [141]. The synthesis of certain aporphines by photolytic cyclization of 1-benzylisoquinolines has been reported [143], [144]. In addition, aporphines have been synthesized in a biogenetic-type sequence by phenolic oxidation of 1-benzylisoquinoline precursors [145–152]. Developments in the synthesis of aporphine alkaloids are reviewed in [153].

Physical Properties.

Corytuberine (**168**) [*517-56-6*], $C_{19}H_{21}NO_4$, M_r 327: *mp* 240 °C (decomp.), $[\alpha]_D^{20}$ +283° (ethanol). Hydrochloride: *mp* 250 °C, $[\alpha]_D^{20}$ +168° (water).

Isothebaine (**169**) [*568-21-8*], $C_{19}H_{21}NO_3$, M_r 311: *mp* 203–204 °C, $[\alpha]_D^{18}$ +285° (ethanol).

Pharmacological Properties. Glaucine (**167**) brings about slight narcosis in animals, but the narcosis is interrupted by epileptiform convulsions. Glaucine also is a depressant for the heart and blood vessels and can damage striated muscle. Corytuberine (**168**) does not induce narcosis in frogs but does induce increased reflex irritability. In warm-blooded animals it causes tonic convulsions and stimulates the secretion of saliva and tears. It also slows the pulse rate by vagus action, increasing the blood pressure during convulsions.

Bulbocapnine (**171**) phosphate is sometimes used in the treatment of paralysis agitans and St. Vitus' dance.

9.10. Protoberberine Alkaloids

Structure and Synthesis. Coreximine (**172**) and xylopinine (**174**) are 2,3,10,11-tetraoxygenated protoberberines, whereas scoulerine (**173**) and canadine (**175**) are 2,3,9,10-tetraoxygenated. Kikemanine (**176**) and capaurimine (**177**), isolated from *Corydalis pallida var. tenuis* [154], possess a methoxy group at C-9 and a hydroxyl group at C-10. Oritentalidine (**178**), isolated from *Papaver* species [155], [156], has a fused *m*-dioxin system on ring D. Coryenchirine (**179**) carries a methyl group at the C-8 position. Berberine (**180**) and palmatine (**181**) are the dehydro quaternary bases. The structure that was initially proposed for capaurimine [157], was revised to **177** on the basis of spectroscopic [158] and synthetic studies [159] confirmed by X-ray analysis [160].

NMR [161], UV spectroscopy, and mass spectrometry have also been used to elucidate the structure of protoberberines. The chirality was established by correlation with (−)-*N*-norlaudanosine [82], and the conformation was determined by IR spectroscopy (Bohlmann bands in the region 2850–2750 cm^{-1}) [162], ^1H NMR [163], ^{13}C NMR [164], optical rotatory dispersion [165], and relative rates of quaternization [166].

181 Palmatine

Tetrahydroprotoberberines have been synthesized for the most part from benzyltetrahydroisoquinolines and formaldehyde by the Pictet-Spengler reaction. Under the usual conditions, involving an acid catalyst, benzyl moieties containing methoxy groups cyclize mainly to 10,11-substituted products, whereas those with hydroxyl functions yield a mixture of 9,10- and 10,11-disubstituted tetrahydroprotoberberines. To favor formation of the 9,10-isomers, pH has been carefully controlled [167–170] or the alternate site of cyclization blocked by a bromine substituent [171]. For example, the phenolic benzylisoquinoline **139** and formaldehyde cyclized at low pH to the 10,11-disubstituted protoberberine, racemic coreximine (**172**), whereas buffer control at pH 6.3 afforded racemic scoulerine (**173**) as the main product. The latter was also obtained when the bromosubstituted precursor **182** was cyclized under the usual mineral acid conditions and the resulting bromo intermediate **183** reductively dehalogenated.

The isomeric 10,11-disubstituted tetrahydroprotoberberines have also been synthesized by the modified Pomeranz-Fritsch reaction [172] and photocyclization of 2-acetyl-1-benzylideneisoquinolines [173]. KAMETANI and his coworkers [174] converted the 1-benzocyclobutenyl-3,4-dihydroisoquinoline (**185**) by thermolysis into the protoberberine (**186**), which was reduced to give xylopinine (**174**).

186

Palmatine (**181**) [*3486-67-7*], $C_{21}H_{22}NO_4$, M_r 369. Iodide: *mp* 239 °C (decomp.). Nitrate: *mp* 239 °C (decomp.).

Pharmacological Properties. Berberine (**180**) is moderately toxic to larger animals, causing cardiac damage, dyspnoea, lowered blood pressure, and paresis in rabbits. After oral administration to humans large amounts appear in the urine. It has some trypanocidal action and has been used as an adjunct to quinine in the treatment of malaria.

Therapeutic Use of Canadine: Sedative, muscle relaxant.

Therapeutic Use of Berberine: Bitter stomachic, antibacterial, antimalarial, and antipyretic.

Trade Names for Berberine Chloride: Pheroberine (Kanebo). *Sulfate:* Sutopunine (Kyorin).

9.11. Protopine Alkaloids

Structure and Synthesis. The protopine alkaloids such as protopine (**187**) and cryptopine (**188**) contain a ten-membered ring system which undergoes a transannular reaction between the basic nitrogen and the carbonyl function to form protoberberines. This transformation and classical degradation have been used to elucidate the structure of these alkaloids.

187 Protopine

188 Cryptopine

Two general methods have been utilized for the synthesis of protopines, both based on the transformation of protoberberines [175], [176].

Physical Properties.

Protopine (**187**) [*130-86-9*], $C_{20}H_{19}NO_5$, M_r 353: *mp* 208 °C. Methiodide: *mp* 217 °C (decomp.).

Cryptopine (**188**) [*482-74-6*], $C_{21}H_{23}NO_5$, M_r 369: *mp* 220 – 221 °C.

Pharmacological Properties. The alkaloids have been shown to possess an inhibiting action on isolated frog heart, muscle, or nerve and a stimulating action on guinea-pig intestine.

9.12. Phthalide Alkaloids

Structure and Synthesis. Hydrastine (**189**) and narcotine (**190**) are representative phthalide alkaloids. Aobamidine (**191**) is a seco form.

189 Hydrastine

190 Narcotine

191 Aobamidine

The structures of the phthalides, exemplified by (−)-β-hydrastine (**189**), are characterized by a δ-lactone joined at the C-1 position of the tetrahydroisoquinoline ring. This structure was determined by mild oxidative cleavage and conversion into known protoberberine alkaloids [177]. The absolute configurations have been assigned by chemical and physical methods [178] and confirmed by X-ray analysis [179].

The phthalideisoquinolines **190** have been classically synthesized as a mixture of two diastereoisomers [180], [181].

Physical Properties.

Hydrastine (**189**) [*118-08-1*], $C_{21}H_{21}NO_6$, M_r 383: *mp* 132 °C, $[\alpha]_D^{20}$ − 50 ° (ethanol), $[\alpha]_D$ − 85 ° (acetone). Hydrochloride: *mp* 116 °C, $[\alpha]_D^{17}$ + 127 ° (dilute hydrochloric acid).

Narcotine (Noscapine) (**190**) [*128-62-1*], $C_{22}H_{23}NO_7$, M_r 413: *mp* 176 °C. Camphorsulfonate: *mp* 188 – 191 °C, $[\alpha]_D^{33}$ + 32.7 ° (water).

Pharmacological Properties. Hydrastine (**189**) causes strychnine-like convulsions in the frog. When large doses are administered, sometimes the convulsions are followed by paralysis. It has been employed on occasion as an internal styptic in uterine haemorrhage. Narcotine (**190**) resembles thebaine in its action, being a reflex stimulant rather than a narcotic.

Therapeutic Use of Hydrastine Hydrochloride: uterine hemostatic, antiseptic.

Therapeutic Use of Narcotine: Antitussive.

Trade Names for Narcotine: Tuscapine (Fisons), Narcotine (Taisho, Hishiyama, Fusso), Noscapine (Nakakita). *Hydrochloride:* Capval (Dreluso), Codipect (Kwizda), Lyobex (Lappe), Narotussin (Bidogici Italia, Ebewe), Nectaclon (Merck), Narcotine M (Isei). *Resinate:* Capval (Dreluso).

9.13. Ochotensine and Related Alkaloids

Ochotensine (**192**), fumaricine (**193**), raddeanine (**194**), and raddeanone (**195**) contain the 1,1-spirobenzylisoquinoline structure. The structure of ochotensine was elucidated by a combination of Hofmann and Emde degradations and NMR, and confirmed by X-ray analysis of ochotensine methiodide [182].

Ochotensine (**192**) has been synthesized by the Pictet-Spengler reaction [183], [184]. SHAMMA and his co-workers converted the protoberberine-type compound into the ochotensine derivative [185], while KAMETANI and his associates synthesized it by thermolysis of benzocyclobutene [186].

9.14. Rheadan Alkaloids

Structure, Occurrence, and Synthesis. Rhoeadine (**196**), alpinigenine (**197**), and oreogenine (**198**), found in *Papaver* species, are representative rheadan alkaloids. Stepinonine (**199**), isolated from *Stephania japonica* [187], is a dimeric alkaloid having a seven-membered nitrogen-containing ring.

The structure of the rheadan alkaloids was elucidated by a combination of Hofmann degradation and spectroscopic methods and confirmed by X-ray analysis [188].

The first synthesis of rhoeadine (**196**) was accomplished via a spirobenzylisoquinoline derivative by IRIE [189]. Several other synthetic methods [190–192] leading to rheadan alkaloids have been developed.

9.15. Morphine and Related Alkaloids

Structure and Synthesis. Representative morphine alkaloids are morphine (**200**), codeine (**201**), thebaine (**202**), salutaridine (**203**), pallidine (**204**), flavinantine (**205**), and sinomenine (**206**). The structures of these alkaloids were elucidated by a combination of Hofmann degradation and IR, UV, NMR, and mass spectroscopies. Absolute configuration was determined by optical rotatory dispersion [193], [194].

In contrast to the protoberberine and related alkaloids, which originate from (+)-reticuline, morphine is derived from the antipodal benzylisoquinoline (−)-reticuline. Reticuline undergoes an alternate coupling mode involving bond formation between the benzyl moiety and the C-4 a position to give the morphinandienone alkaloids flavinantine (**205**) [195] and salutaridine (**203**). The latter is the biogenetic precursor of morphine [196].

Total synthesis of morphine (**200**) was achieved first by GATES [197] and then by GINSBURG [198]. It has also been prepared by BARTON and his associates [199] with biogenetic-type sequences. KAMETANI and his associates reported the synthesis of the key intermediate salutaridine (**203**) by the Pschorr reaction of the aminoisoquinoline **207** [200] as well as by photolysis of 2′-bromoreticuline (**208**, racemic mixture) [201].

Physical Properties.
Morphine (**200**) [*57-27-2*], $C_{17}H_{19}NO_3$, M_r 285: *mp* 254 °C (decomp.). Monohydrate: *mp* 254 – 256 °C (decomp.), $[\alpha]_D^{25}$ − 132 ° (methanol). Hydrobromide [*630-81-9*]: $[\alpha]_D^{15}$ − 100.4 ° (water). Hydrochloride [*52-26-6*]:

206 Sinomenine

207

208

Codeine

Thebaine (**202**) [*115-37-7*], $C_{19}H_{21}NO_3$, M_r 311: *mp* 193 °C, $[\alpha]_D^{15}$ −219° (ethanol), $[\alpha]_D^{23}$ −230° (chloroform).

Salutaridine (**203**) [*1936-18-1*], $C_{19}H_{21}NO_4$, M_r 327: *mp* 197–198 °C, $[\alpha]_D^{12}$ +114° (methanol).

Sinomenine (**206**) [*115-53-7*], $C_{19}H_{23}NO_4$, M_r 329: *mp* 161 °C, $[\alpha]_D^{26}$ −71° (methanol). Hydrochloride: *mp* 231 °C (decomp.), $[\alpha]_D^{17}$ −82° (water).

Preparation. One method for the production of morphine and codeine starts from finely powdered poppy plants [202]. The plants are extracted with quicklime in a suitable solvent. After separating the extract and washing the residue, the filtered solution is acidified, freed from the solvent in vacuo, and the residue extracted at a pH of ca. 9 with amyl alcohol or another suitable organic solvent. Morphine and codeine are obtained from this extract with dilute acid.

New variations are described in [203].

Pharmacological Properties. *Morphine* (**200**) exerts both marked depressing and marked stimulating effects on the central nervous system. The depression affects the brain, particularly the sensation of pain and respiration. The cerebral motor functions are less affected. Pharmacologically, *codeine* (**201**) resembles morphine but is less toxic, and its depressant action is less marked and prolonged. Its stimulating action involves not only the spinal cord but also the lower parts of the brain.

Sinomenine (**206**) produces increased reflex excitability and respiratory paralysis in mice, frogs, and rabbits.

Therapeutic Use: Morphine is used as a narcotic analgesic; codeine is used as a narcotic analgesic and antitussive.

Trade Names for Morphine: Duromorph (L. A. B.), Nepenthe (Evans). *Sulfate:* Morphine Sulfate (Elkins-Sinn, Philips Roxane, Wyeth), MST Continus (Napp). *Hydrochloride:* Morphin-Amphiden "NBK" (Merck, Knoll, Boehringer), Morphin Thilo (Thilo), Ensan Morphine (Sankyo, Shionogi, Dainippon, Takeda, Tanabe). *Tartrate:* Cyclimorph (Calmic).

Trade Names for Codeine: Codeopect (Nyegaard), Codicept (Sanol). *Phosphate:* Codeinfos (Union Quimico-Farmaceutica), Tricodein (Solac, Zyma), Codyl (Boehringer Ingelh.), Codeinum Phosphoricum (Merck, Knoll, Cas-

can, Takeda, Dainippon, Isei, Tanabe, Sankyo, Shionogi). *Resinate:* Codipertussin (Taeschner).

9.16. Hasubanan Alkaloids

The structures of hasubanonine (**209**) and cepharamine (**210**) have been derived by the use of physical methods on the degradation products [204]. The structure of the related, novel halogen-containing alkaloid acutuminine (**211**) was proposed on the basis of spectra and confirmed by X-ray analysis [205].

(±)-Cepharamine (**210**) and (±)-hasubanonine (**209**) have been synthesized via Robinson annelation [206], [207]. Photolytic and phenolic oxidative methods have been used to synthesize hasubanan alkaloids [208], [209].

9.17. Emetine and Related Alkaloids

Structure and Synthesis. Protoemetine (**212**), emetine (**213**), and tubulosine (**214**) contain the benzoquinolizidine skeleton. The elucidation of the structure of emetine (**213**) involved a variety of degradative and physicochemical methods as well as biogenetic considerations. The gross structure was proposed by Robinson [210] on the speculation that emetine is biogenetically derived from a protoberberine-type precursor via Woodward fission. The relative and the absolute configurations were determined mainly by Battersby [211] and van Tamelen [212]. Ipecoside (**215**) is a biogenetic precursor of the ipecacuanha alkaloids [213].

214 Tubulosine

Ac = acetyl
Glu = glucose
215 Ipecoside

Emetine has been synthesized by many groups [214–220]. Openshaw [215] obtained the (−)-benzoquinolizidine **218** by the reaction of the 3,4-dihydroisoquinoline **216** and the Mannich base **217** followed by treatment with (−)-camphor-10-sulfonic acid. The ketone **218** was transformed into emetine (**213**) via the unsaturated ester **219**. Furthermore, properly substituted benzo[a]quinolizidine **222** was synthesized in a one-pot reaction from the 1-methyl-3,4-dihydroisoquinoline **220** and dimethyl 3-methoxyallylidenemalonate (**221**) in methanol. (±)-Emetine (**213**) and (±)-tubulosine (**214**) were stereoselectively synthesized from the acetal **222** [218–220].

Physical Properties. *Emetine* (**213**) [*483-18-1*], $C_{29}H_{40}N_2O_4$, M_r 480: *mp* 74 °C, $[\alpha]_D^{20}$ −50° (chloroform). Hydrochloride [*316-42-7*]: *mp* 235–255 °C, $[\alpha]_D$ +11° (water).

Preparation. Emetine is produced on an industrial scale by both synthesis and isolation from roots of Ipecacuanha. The powdered drug is alkalized with ammonia and then extracted with ether. The base is neutralized with aqueous sulfuric acid, and then the solution is alkalized with sodium hydroxide and potassium hydroxide and extracted again with ether, whereby the emetine goes into the ether phase. After evaporation, the residue of the ether phase is dissolved in methanol and mixed with ethanolic hydrobromic acid to crystallize emetine hydrobromide. From 120 to 200 kg of *Radix ipecacuanha* are required to produce one kilogram of raw emetine hydrobromide.

Pharmacological Properties and Therapeutic Use. Emetine (**213**) is employed as an antiamebic and is sometimes employed as an emetic. In small doses it is used as an expectorant although more commonly ipecacuanha itself or one of its galenical preparations is employed.

Trade Names for the Hydrochloride: Emetine (City Chem. Corp., Inland Alkaloid Co., Lilly, Upjohn), Emetinum Hydrochloricum (Riedel).

9.18. Erythrina Alkaloids

Structure and Synthesis. The erythrina alkaloids are characterized by a tetracyclic spiro amine system containing either two conjugated double bonds or a single unsaturated bond. One of the rings is either aromatic or a δ-lactone. The three major types are exemplified by erysotrine (**223**), erythratine (**224**), and α-erythroidine (**225**). The elucidation of the structures of these alkaloids, summarized in an excellent review by Mondon [221], involved the efforts of many investigators and utilized almost all available physicochemical methods.

The total synthesis of the erythrina alkaloid erysotrine (**223**) was achieved by Mondon and Nestler [222]. A total synthesis of (+)-erysotrine (**223**) is reported in [223].

On the basis of biogenetically patterned sequences [224] racemic dihydroerysodine (**226**) and erythratidine (**227**) were synthesized.

223 Erysotrine

224 Erythratine

225 α-Erythroidine

226

227

Physical Properties.

α-Erythroidine (**225**) [*466-80-8*], $C_{16}H_{19}NO_3$, M_r 273: *mp* 58 – 60 °C, $[\alpha]_D^{27}$ + 136 ° (water). Hydrochloride: *mp* 226 – 228 °C, $[\alpha]_D^{32}$ + 118 ° (water).

9.19. Cephalotaxine Alkaloids

Cephalotaxine (**228**), isolated form *Cephalotaxus harringtonia var. drupacae,* possesses a characteristic 1-azaspiro[4.4]nonene structure. Harringtonine (**229**) is an ester derivative. Cephalotaxine (**228**) was synthesized by WEINREB [225], SEMMELHACK [226], [227], and IKEDA [228].

Pharmacological Property. Harringtonine (**229**) shows a potential antitumor activity [229].

228 R = H Cephalotaxine

229
Harringtonine

9.20. Protostephanine Alkaloids

Protostephanine (**230**), isolated from *Stephania japonica,* contains a dibenz[*d,f*]azocine system. The nine-membered heterocyclic protostephanine has been prepared by classical methods [230] and a biosynthetic pathway [231].

230 Protostephanine

9.21. Benzophenanthridine Alkaloids

Structure, Origin, and Synthesis. Representative benzophenanthridine alkaloids are nitidine (**231**), sanguinarine (**232**), chelidonine (**233**), and corynoline (**234**). All were isolated from *Papaveraceae* plants.

Benzophenanthridine alkaloids have been synthesized by the general procedure developedby BAILEY and co-workers [232] as well as by methods which used the Pschorr reaction [233], thermolysis [234], and photolysis [235].

The structure of corynoline (**234**), isolated from *Corydalis incisa,* was confirmed by an X-ray analysis of the *p*-bromobenzoate [236]. Corynoline was synthesized by two different methods: the photocyclization of enamides [237] and the condensation of a piperonylidenemethylamine with a substituted homophthalic anhydride [238].

231 Nitidine

232 Sanguinarine

233 Chelidonine

234 Corynoline

Physical Properties.
Chelidonine (**233**) [*476-32-4*], $C_{20}H_{19}NO_5$, M_r 353: *mp* 135 – 136 °C, $[\alpha]_D^{22}$ +115° (ethanol), $[\alpha]_D^{20}$ +117° (chloroform).
Sanguinarine (**232**) [*2447-54-3*], $C_{20}H_{14}NO_4$, M_r 332: *mp* 278 – 280 °C (from water), *mp* 210 – 211 °C (from chloroform + ethanol).

Pharmacological Property. Sanguinarine (**232**) produces glaucoma in animals.

9.22. Dibenzopyrrocoline Alkaloids

The dibenzopyrrocoline alkaloids, isolated from Australian *Lauraceae* plants, have a five-membered ring system containing a shared quaternary nitrogen. This is exemplified by cryptowoline (**235**). This representative alkaloid was synthesized by oxidative coupling of laudanosine before it was isolated from nature [239].

235 Cryptowoline

9.23. Phenethylisoquinoline Alkaloids

Structure and Synthesis. Various types of phenethylisoquinoline alkaloids have been found in nature. For example, autamnaline (**236**), melanthioidine (**237**), kreysiginone (**238**), multifloramine (**239**), androcymbine (**240**), and schelhammerine (**241**) are the homologues of the corresponding 1-benzylisoquinoline, bisbenzylisoquinoline, proaporphine, aporphine, morphine, and erythrina alkaloids, respectively. Colchicine (**242**) is also included in this class for biogenetic reason.

236 Autumnaline

237 Melanthiodine

238 Kreysiginone

239 (−)-Multifloramine

240 Androcymbine

241 Schelhammerine

242 Colchicine

Although the biosynthesis of all the phenethylisoquinoline alkaloids has not yet been fully elucidated, the probable pathways have been indicated by tracer experiments for homomorphinandienones and homoaporphines. Strong evidence was provided for the route by which the homomorphinandienone alkaloid androcymbine (**240**), itself derived from the phenethylisoquinoline **236**, is transformed into colchicine (**242**) [240].

Bisphenethylisoquinoline melanthioidine (**237**) has been synthesized by a double Ullmann reaction [241], [242]. In addition, a biogenetic route to **237** via phenol oxidation has been studied [243].

Phenol oxidation has also been used in the synthesis of the homoaporphines [244–246]. Androcymbine (**240**) was obtained by photolytic dehydrobromination [247] and the photo-Pschorr reaction [248]. Colchicine (**242**) has been synthesized by a number of methods [249–253].

Physical Properties.

Colchicine (**242**) [*64-86-8*], $C_{22}H_{25}NO_6$, M_r 399: *mp* 142 – 150 °C, *mp* 157 °C, $[\alpha]_D^{17}$ – 121 ° (chloroform).

Preparation. The seeds of the meadow saffron (*Colchicum autumnale* L.) are extracted with boiling alcohol to obtain colchicine. Because of its solubility, it can be separated from accompanying substances: the extract is evaporated and the residue mixed with water. The undissolved resins and fats are filtered off and the filtrate extracted with chloroform. After evaporation of the chloroform solution the procedure is repeated with the residue. When the purity is sufficient, the colchicine crystallizes from the concentrated chloroform solutions as a chloroform complex [254].

Pharmacological Properties. Colchicine (**242**) has no direct action upon the heart but is a capillary poison, among other things. Large doses cause paralysis ascending the central nervous system and accompanied by vasomotor and respiratory paralysis.

Therapeutic Use: Gout suppressant, treatment of familial Mediterranean fever.

Trade Names: Colchicine (Lilly, Danbury Pharm., Purepac Pharm., Shionogi, Tokyo Tanabe).

9.24. Miscellaneous Isoquinoline Alkaloids

Structure and Synthesis. The structure of mimosamycin (**243**), isolated from *Streptomyces lavendulae,* was determined by X-ray analysis [255]. Mimosamycin (**243**) has been synthesized via Pomeranz-Fritsch reaction [256]. On the other hand, the structure of saframycin B (**244**) also isolated from *S. lavendulae,* was elucidated by comparison of spectra of saframycin B and its congener saframycin C. The structure of the congener had been determined previously by X-ray crystallography [257]. The first synthesis of (±)-saframycin B was carried out by FUKUYAMA and SACHLEBEN [258].

243 Mimosamycin

244 Saframycin B

Pharmacological Properties. Mimosamycin (**243**) and saframycins show antibiotic activity against gram-positive bacteria. Saframycins also exhibit antitumor activities.

10. Amaryllidaceae Alkaloids

A large number of alkaloids isolated from *Amaryllidaceae* species are classified by their biogenetic origin from norbelladine (**245**) into five groups (Sections 10.1, 10.2, 10.3, 10.4, 10.5) [259], [260]. The tracer experiment by BARTON and COHEN showed that **245** was derived from tyrosine and phenylalanine, and that lycorine (**250**) and haemanthamine (**259**) originate from **246** via o,p′- and p,p′-oxidative coupling, respectively. Galanthamine (**265**) is formed from **247** by p,o′ coupling [126], [261–264].

245 Norbelladine

246 R = H
247 R = CH_3

10.1. Lycorine Type

Structure. The structure, including the absolute stereochemistry, of lycorine has been worked out on the basis of spectra, chemical degradations, and finally X-ray analysis, to be **250** [265]. The synthesis of the lycorine skeleton **249** of correct stereochemistry (B and D are *trans*) was achieved elegantly by STORK in 1979 [266], employing an intramolecular Diels-Alder reaction of the amide **248**. Many papers concerned with the synthesis of this group of alkaloids have appeared [267–269], [270–272].

248 → **249**

Pulviine (**251**) possesses a structure similar to that of lycorine, and it could be converted into lycorenine (**252**) in several steps. Reduction with lithium aluminum hydride, tosylation of the benzylic OH group, cyclization, and demethylation transforms **252** into **251**, thus establishing the stereochemistry of both alkaloids. Since pretazettine (**253**) also has a *trans* B – D ring juncture, it was classified in this group. Pretazettine (**253**) is converted to tazettine on heating in water at 70 °C.

250 (−)-Lycorine

251 (−)-Pulviine

252 (+)-Lycorenine

253 (+)-Pretazettine

Physical Properties.
Lycorine (**250**) $C_{16}H_{17}NO_4$, M_r 287: *mp* 275 – 280 °C decomp. (from ethanol), $[\alpha]_D^{16}$ − 129 ° (98 % ethanol).

Pharmacological Properties. The alkaloids in this group are relatively nontoxic to mammals. Lycorine given orally or subcutaneously in large doses to the dog or cat causes vomiting and diarrhea. Blood pressure does not seem to be affected.

10.2. Crinane Type

The structure of crinine (**254**) was elucidated by Hofmann degradation of oxocrinine (**255**) to give the dienone **256**. Reduction then provided the tetrahydro derivative **257** [273]. The stereochemistry of maritidine (**258**), a tertiary base containing two methoxy groups and an allyl alcohol function, was established [274] on the basis of optical rotatory dispersion and circular dichroism curves. The absolute configuration of crinane alkaloids was finally solved by X-ray analysis of a haemanthamine (**259**) derivative [275].

254 (−)-Crinine →

255 →

256 **257**

258 (+)-Maritidine **259** (+)-Haemanthamine

10.3. Nariclasine Type

Structure and Synthesis. Lycoricidine (**260**) and lycoricidinol (**261**) possess potent biological activity and were isolated from the bulbs of *Lycoris radiata* Hebb. Their structures, excluding stereochemistry, were elucidated by spectroscopic and chemical evidence [275]. Lycoricidine (**260**) may be derived biogenetically from **254** by phenolic coupling and subsequent degradation of **262**. Narciclasine (**261**), which is identical with lycoricidinol, was also isolated from *Narcissus incomparabilis* and all *Narcissus* sp. The structure was determined by spectral data [276] and X-ray analysis [277]. Later, pancratistatin (**264**), which is more highly functionalized with hydroxyl groups, was found in the roots and bulbs of *Pancratium littorale* [278].

The first total synthesis of (±)-pancratistatin (**264**) was achieved by DANISHEFSKY [279]. The syntheses of optically active lycoricidine (**260**) [280], narciclasine (**261**) [281], pancratistatin (**264**), [282], [283] and 7-deoxypancratistatin (**263**) [284], [285] have been reported.

260 R = H Lycoricidine
261 R = OH Narciclasine (Lycoricidinol)
263 R = H 7-Deoxypancratistatin
264 R = OH Pancratistatin

262 **260**

Physical Properties.
Lycoricidine (**260**) [*19622-83-4*], $C_{14}H_{13}NO_6$, M_r 291: *mp* 214.5 – 215.5 °C.
Narciclasine (**261**) [*29477-83-6*], $C_{14}H_{13}NO_7$, M_r 307: *mp* 232 – 234 °C (decomp.), $[\alpha]_D$ + 145 ° (c = 1.5 in ethanol).
Pancratistatin (**264**) [*96203-70-2*], $C_{14}H_{15}NO_8$, M_r 325: *mp* 322 – 324 °C (from DMF – methanol – diethyl ether), $[\alpha]_D$ + 48 ° (c = 1.0 in dimethyl sufoxide).

Pharmacological Properties. Lycorocidine (**260**) acts as a plantgrowth regulator and inhibits division of Ehrlich ascites cells. Narciclasine (**261**) is a strong tumor inhibitor [LD_{50} 5 mg/kg (s.c. mice)]. In addition, pancratistatin (**264**) has remarkable inhihitory activity against P-388 leukaemia cells (ED_{50} 0.01 µg/mL) and M 5076 sarcoma (53 – 84 % life extension at 0.38 – 3.0 mg/kg).

10.4. Galanthamine Type

Structure and Synthesis. The structure of galanthamine (**265**) was elucidated by the reaction with concentrated hydrobromic acid to yield the catechol. The dimethyl ether of this catechol was then subjected to Emde degradation, and the oxidation of the resulting phenethylamine (**267**) provided galanthamic acid (**268**) and the monocarboxylic acid **269** [286]. Moreover, manganese dioxide oxidation of galanthamine afforded narwedine (**266**) [287]. The structure of **265** was confirmed by X-ray analysis, including its absolute configuration [288]. The first synthesis of galanthamine via a biogenetically patterned pathway by phenolic coupling of belladine (**247**) was reported by BARTON [289]. Since then, many attempts to synthesizes galanthamine have been reported, because of its pharmacological activity [290–292].

265 R = H β-OH (−)-Galanthamine
266 R = O Narwedine

267

268 R = CO_2H **269** R = CH_3

Physical Properties.

Galanthamine (**265**) [*357-70-0*], $C_{17}H_{21}NO_3$, M_r 287: *mp* 126 – 127 °C (from benzene), $[\alpha]_D^{20}$ – 188.8 ° (*c*= 1.378 g/ 100 ml in ethanol).

Narwedine (**266**) [*510-77-0*], $C_{17}H_{19}NO_3$, M_r 285, *mp* 189 – 192 °C, $[\alpha]_D$ +405 ° (*c* = 1.0 in chloroform).

Pharmacological Properties. Galanthamine inhibits acetylcholinesterase activity and is sold in the USSR. LD_{50} in mice: 8.0 mg/kg i.v., 18.7 mg/kg orally.

Therapeutic Use: Cholinesterase inhibitor.

Trade Names: Nivalin (Chimimport, Bulgaria), Nivalin (Werfft Chemie, Austria), Galanthamin (Diamant).

10.5. Montanine Type

Structure and Synthesis. The montanine-type alkaloids montanine (**271**), pancracine (**272**), and coccinine (**273**) have a unique structure with a 5,11-methanomorphanthridine skeleton. The new montanine-type alkaloid montabuphine (**274**) with a 5,11-methanomorphanthridine skeleton was isolated from the bulbs of *Boophane flava*, and its structure was determined on the basis of spectroscopic considerations [293]. The total syntheses of **271** – **273** were reported by Hoshino [294], Overman [295], and Weinreb [296].

Physical Properties.

Montanine (**271**) [*642-52-4*], $C_{17}H_{19}NO_4$, M_r 301: oil, monohydrate, *mp* 88 – 89 °C (from water), $[\alpha]_D^{26}$ – 97.6 ° (*c* = 0.57 in chloroform); acetone solvate, *mp* 57 – 60 °C (acetone); chloroform solvate, *mp* 59 – 65 °C (chloroform). Weak hypotensive and convulsive agent (dog); LD_{50} 42 mg/kg (i.v. dog).

Pancracine (**272**) [*21416-14-8*], $C_{16}H_{17}NO_4$, M_r 287: *mp* 272 – 273 °C (mehtanol), $[\alpha]_D^{25}$ – 74 ° (*c* = 0.02 in methanol).

Coccinine (**273**) [*132242-50-3*], $C_{17}H_{19}NO_4$, M_r 301: *mp* 162 – 163 °C, $[\alpha]_D^{27}$ – 189 ° (*c* = 1.9 in ethanol). Convulsive action at high doses; LD_{50} 17.5 mg/kg (i.v. dog).

Montabuphine (**274**) [*168611-77-6*], $C_{17}H_{19}NO_4$, M_r 301: *mp* 162 – 164 °C, $[\alpha]_D^{22}$ + 157 ° (*c* = 0.106 in ethanol).

10.6. Miscellaneous

The structures of mesembrine (**275**) and joubertiamine (**276**) were evident from their spectral properties. The absolute configuration of **275** was confirmed by X-ray analysis [297]. Biosynthetic studies for the alkaloids of this family were carried out by tracer work. There are a number

of reports concerning the synthesis of this family of alkaloids [298], [299]. The first synthesis of **275** was reported by SHAMMA in 1965.

275 Mesembrine

276 Joubertiamine

Physical Properties.

Mesembrine (**275**) $C_{17}H_{23}NO_3$, M_r 289: *bp* 186–190 °C (at 0.04 kPa), $[\alpha]_D^{20}$ −55.4° (methanol).

Mesembrine shows local anaesthetic and mydriatic activities. Asymmetric syntheses of **275** have been performed [300–302].

Cherylline, isolated from several *Crinum* species [303], was assigned structure **277**, which possesses a *p*-hydroxyphenyl group at the C-4 position on the basis of spectroscopic and chemical considerations. Biogenetically, cherylline might arise from **246** via the quinone methide **278** by cyclization. An alternate pathway involves mantanine-type intermediate **279** arising from **246** by phenolic oxidative coupling and rearrangement of the 5,10*b*-ethanophenanthridine skeleton. Acid-catalyzed cyclization of **280** led to cherylline via the quinone methide **278** [304].

11. Indole Alkaloids

Indole alkaloids constitute the largest group of alkaloids. They are of interest on account of their structures – often extremely complex – and their surprising physiological activities. Most contain a tryptamine unit as a readily distinguishable feature or a modified structure, and tryptamine is a precursor in the biosynthesis of many of these alkaloids.

11.1. Non-Tryptamine Type

Mukonine (**281**) was isolated from the stem bark of *Murraya koenigii* Spreng. It is the methyl ester of mukonic acid (1-methoxycarbazole-3-carboxylic acid) [305]. Mupamine (**282**), isolated from *Clausena anisata* (Willd.) Oliv., was characterized as a pyranocarbazole alkaloid on the basis of its spectra [306].

277 (−)-Cherylline

278

279

280

281 Mukoine

282 Mupamine

11.2. Non-Isoprenoid Type

Tryptamine (**283**) and serotonin (**284**) represent the basic skeleton and are biosynthetic precursors for this group of alkaloids. Harmine (**285**) is a typical β-carboline alkaloid. Although the structure relationship between physostigmine (**286**) and tryptophan appears obscure, it is also included in this group. Also calycanthine (**287**) does not possess a tryptamine structure as a distinguishable feature; however, it is included in an indole alkaloid because most of its congeners are tryptamine derivatives.

283 R = H Tryptamine
284 R = OH Serotonin

285 Harmine

286 Physostigmine (Eserine)

287 Calycanthine

288 Harmaline

Physical Properties.

Harmine (**285**) [*442-51-3*], $C_{13}H_{12}N_2O$, M_r 212: *mp* 261 °C decomp. (from methanol).

Physostigmine (**286**) [*57-47-6*], $C_{15}H_{21}N_3O_2$, M_r 275: *mp* 105 – 106 °C (from ether or benzene), $[\alpha]_D^{17}$ − 76 ° (chloroform), $[\alpha]_D^{25}$ − 120 ° (benzene).

Harmaline (**288**) [*304-21-2*], $C_{13}H_{14}N_2O$, M_r 214: *mp* 229 – 231 °C (from ethanol).

Pharmacological Properties. Harmine is less toxic than harmaline. Harmaline brings about tremors and convulsions in moderate doses. Lethal doses in mammals cause respiratory paralysis and decreased body temperature. The contraction of most kinds of smooth muscle is diminished. An exception is uterine muscle. A large number of doses reduce blood pressure by weakening the cardiac muscle [307]. Physostigmine is known to be a cholinesterase inhibitor. It stimulates the central nervous system and causes respiratory paralysis. Large doses reduce blood pressure, cause a convulsion of skeletal muscles, and act as a cardiac depressant. Its sulfate and salicylate are used medically. The effects of calycanthine resemble those of strychnine: calycanthine stimulates the spinal cord but depresses the heart. Its hydrochloride reduces blood pressure and cardiac contraction in anaesthetized cats. LD_{50} i.v. in mice: 38 mg/kg for harmine. LD_{50} i.p. in mice: 0.64 mg/kg for eserine salicylate. LD_{50} s.c. in rats: 120 mg/kg for harmaline.

11.3. Isoprenoid Type

11.3.1. Mould Metabolites

Brevianamide E (**289**) [308], isolated from culture medium of *Penicillium brevicompactum,* is a toxic mould metabolite. Structure **289** was proposed mainly on the basis of spectroscopic evidence and plausible biogenetic argument. Its absolute configuration was confirmed by the total synthesis from L-tryptophan [309]. Echinuline (**290**) and aurechinuline (**291**) [310] are also toxic fungi metabolites. They are isolated from several *Aspergillus* species. Characteristic features of these alkaloids are isopentenyl groups on the aromatic ring and a diketopiperazine ring.

289 Brevianamide E

290 Echinuline

291 Aurechinuline

11.3.2. Ergot Alkaloids

Structure, Occurrence, and Synthesis. Lysergic acid (**292**) and isolysergic acid (stereoisomers in respect to the carboxyl group at the 8-position) are the main cleavage components of ergotamine-type alkaloids. Agroclavine (**293**) [311] was isolated from the mycelium of *Claviceps purpurea*. Clavine-type alkaloids, which are tricyclic ergot alkaloids, were found in several *Claviceps* species. Chanoclavine I (**294**) [312] and chanoclavine II (**295**) [313] were shown to be stereoisomers in respect to substituents on ring C. Ergotamine (**296**) [314] and ergosine (**297**) [315] contain a peptide unit in which the amino acid components are different. Paliclavine (**298**) [313] is an allyl alcohol rearrangement product of chanoclavine. Chemical correlation of these alkaloids (**292**–**295**), e.g. catalytic reduction over palladium, allowed elucidation of the structures of these natural products.

Many reports concerning synthesis have appeared.

Physical Properties.

Lysergic acid (**292**) [*82-58-6*], $C_{16}H_{16}N_2O_2$, M_r 268: *mp* 238 °C (from water), $[\alpha]_D^{20}$ +32° (pyridine).

Isolysergic acid, $C_{16}H_{16}N_2O_2$, M_r 268: *mp* 218 °C.

Ergocristine (**296**) [*511-08-0*], $C_{35}H_{39}N_5O_5$, M_r 609: prisms, *mp* 160–175 °C decomp. (from acetone), $[\alpha]_D^{20}$ −280° (*c* = 1.0 g/100 ml in chloroform).

Ergocryptine (**299**) [*511-09-1*], $C_{32}H_{41}N_5O_5$, M_r 575: prisms, *mp* 210–212 °C (from methanol), $[\alpha]_D^{20}$ −191° (*c* = 1.0 g/100 ml in chloroform).

Ergocornine (**300**) [*564-36-3*], $C_{31}H_{39}N_5O_5$, M_r 561: *mp* 182–184 °C decomp. (from methanol), $[\alpha]_D^{20}$ −186° (*c* = 1.0 g/100 ml in chloroform).

9,10-Dihydroergotamine [*511-12-6*], $C_{33}H_{37}N_5O_5$, M_r 583: prisms, *mp* 239 °C (from aqueous 90 % acetone), $[\alpha]_D^{20}$ −64° (pyridine).

9,10-Dihydroergocristine [*17479-19-5*], $C_{33}H_{41}N_5O_5$, M_r 611: hexagonal plates, *mp* 180 °C (from acetone), $[\alpha]_D^{20}$ −56° (pyridine).

9,10-Dihydroergocryptine [*17479-14-0*], $C_{32}H_{43}N_5O_5$, M_r 577: plates or polyhedrons, *mp* 235 °C (from ethanol), $[\alpha]_D^{20}$ −41° (pyridine).

9,10-Dihydroergocornine [*17479-17-3*], $C_{31}H_{41}N_5O_5$, M_r 563: plates, *mp* 187 °C (from ethanol), $[\alpha]_D^{20}$ −48° (pyridine).

N-[1-(Hydroxymethyl)propyl]-lysergamide (Methylergometrine, Methylergonovine) (**303**) $C_{20}H_{25}N_3O_2$, M_r 339: *mp* 172 °C (from benzene), $[\alpha]_D^{20}$ −45° ($c = 0.4$ in pyridine).

N-[1-(Hydroxymethyl)propyl]-1-methyllysergamide (Methysergide), $C_{21}H_{27}N_3O_2$, M_r 353: *mp* 194–196 °C, $[\alpha]_D^{20}$ −45° ($c = 0.5$ in pyridine).

N-Cyclopentyllysergamide, $C_{21}H_{25}N_3O$, M_r 335: *mp* 121–122 °C, $[\alpha]_D^{20}$ −27.9° (pyridine).

Pharmacological Properties. Lysergic diethylamide is a known antagonist to serotonin, and sometimes it causes psychological trouble. Ergolines may be potential inhibitors of prolactin and mammary tumours. Ergotamine stimulates the smooth muscles of only the uterus and blood vessels. Therefore it increases blood pressure by constricting blood vessels. It does not affect other smooth muscles. The tartrate is usually used for relief of migraine. The pharmacology of ergot alkaloids has been reviewed.

Therapeutical Use. Ergocristine: Uterotonic, vasodilator.

Ergocryptine: vasodilator, antihypertensive agent.

Ergocornine: vasodilator, antihypertensive agent.

9,10-Dihydroergotamine: against migraine.

9,10-Dihydroergocristine: antihypertensive agent, vasodilator, against migraine.

9,10-Dihydroergocornine: antihypertensive agent, against migraine.

N-[1-(Hydroxymethyl)propyl]-1-lysergamide: uterotonic.

N-[1-(Hydroxymethyl)propyl]-1-methyllysergamide: antiserotonin activity (migraine, carcinoid syndrome).

N-Cyclopentyllysergamide: Uterotonic.

Trade Names. 9,10-Dihydroergotamine: Dihydergot (Sandoz). *Tartrate:* Eldoral (Dumex). *Methylsulfonate:* Dihydergot (Sandoz), Detms (Rentschler), Dihytamin (Arzneimittelwerk Dresden, Temmler Pharma), Dihydroergotamine (Lafarge), Ergont (Desitin), Ikaran (Sinbio), Séglor (Millot), Tonopres (Boehringer Ingelheim), Dihydergot (Sankyo), Restal (Tokyo Tanabe), Dihygotamine (Kaken).

9,10-Dihydroergocornine: Together with 9,10-dihydroergocristine and 9,10-dihydroergocryptine in a mixed preparation: Hydergin (Sandoz), Hydergin (Sankyo).

N-[1-(Hydroxymethyl)propyl]lysergamide: Methylergobasin, Methylergobrevin (Arzneimittelwerk Dresden), Methylergometrin (Sandoz), Methylergonovin (Burroughs-Wellcome). *Methylergometrin maleinate:* Methergin (Sandoz). *Malate:* Levospan (Isei), Metenarin (Teikoku Zoki), Ryeonovin (Morishita), Spametrin-S (Yamanouchi), Takimetrin-M (Kanebo).

N-[1-(Hydroxymethyl)propyl]methyllysergamide: Deseril (Sandoz), Sandert (Sandoz).

N-Cyclopentyllysergamide: Cepentyl.

11.3.3. Monoterpenoid Alkaloids

Feeding experiments on *Vinca rosea* showed that the non-tryptamine unit of monoterpene alkaloids was derived from two molecules of mevalonic acid. Further investigation suggested that secologanin, derived from geraniol, was a key precursor of these alkaloids. The non-tryptamine part can be of the (**A**) Corynanthe-Strychnos type, (**B**) Aspidosperma type, or (**C**) Iboga type.

11.3.3.1. Corynanthe Group

Vincoside (**304**) and strictosidine (**305**) are stereoisomers at the 3-position. They are synthesized from secologanin by condensation with tryptamine [317]. Vincoside (**304**) was readily converted into vincoside lactam (**308**) by treatment with aqueous sodium carbonate at room temperature, whereas strictosidine (**305**) was transformed into nacycline (**310**) on treatment with methanolic hydrochloric acid [318]. Zenk indicated that terpenoid indole alkaloids of 3β configuration also arise biosynthetically from strictosidine [319]. The biosynthetic conversion proceeds with loss of hydrogen at the 3-position to form the 3α-*Corynanthe* alkaloids, whereas the hydrogen is retained in the 3β series. Corynantheine (**306**) is a typical indole alkaloid bearing an indoloquinolizidine skeleton. Three other

possible diastereomers have been found in nature: hirsuteine, corynantheidine, and spiociliatine. Antirhine [320] was isolated from *Antirrhea putaminosa,* and the structure was assigned as **307**. Strictosidine was correlated chemically with corynantheine and antirhine. The cinchona alkaloid was shown to be derived from corynantheal (**311**) biosynthetically.

11.3.3.2. Heteroyohimbine

Ajmalicine (**312**) is an early stage of alkaloid in the biosynthesis of indole alkaloids from tryptamine and secologanin. It is converted to the oxindole alkaloid mitraphylline (**313**) in *Mitragyna parvifolia* [321].

304 Vincoside

Ajmalicine (**312**) [*483-04-5*], (δ-Yohimbine, Raubasine, Vinceine, Vincain), $C_{21}H_{24}N_2O_3$, M_r 352: colorless prisms (from methanol), *mp* 257 °C (decomp.), $[\alpha]_D^{20}$ − 60 ° (chloroform).

Therapeutic Use: Against central and peripheral ischemia. Antihypertensive reagent and tranquilizer.

Trade Names: Hydrosarpan (Servier), Circolene (Inverni Della Beffa), Sarpan (Farge), Raubaserp (Ethica), Loparol (Boehringer Mannheim).

11.3.3.3. Yohimbine

Occurrence and Synthesis. Yohimbine (**314**) was found in *Corynanthe* and related trees.

Its epimers are known as alloyohimbine (**315**) and α-yohimbine (**316**). Synthesis of yohimbine (**314**) was reported by VAN TAMELEN [322]. Reserpine is a major constituent of *Rauwolfia serpentina*. Alkali hydrolysis of **318** afforded reserpic acid (**317**). WOODWARD [323] reported the stereoselective total synthesis of reserpine (**318**).

314 Yohimbine

315 R = α-CO_2CH_3 Alloyohimbine

Preparation. The isolation of yohimbine from *Pausinystalia Johimbe* (K. Schum.) Pierre (*Corynanthe yohimbe* K. Schum.) is described by F. CHEMNITIUS [324].

The following procedure is suitable for isolating reserpine from *Rauwolfia serpentina* [325]:

Finely powdered roots (750 g) of *Rauwolfia serpentina* Benth. are moistened with water (800 ml) and left to stand for three hours to ensure even moistening and swelling. The drug is then extracted for 20 h with 3 – 4 l of benzene in a

Soxhlet extractor. The benzene extract is shaken three times with 200 ml of 10 % phosphoric acid, and the phosphoric acid solution adjusted to pH 6.5 – 7.0 with hydrogencarbonate. Then this solution is shaken five times with 200 ml of benzene, the benzene extract dried with sodium sulfate, and the solution evaporated in vacuo. A pale foamy residue (4.4 – 5.0 g) remains. Reserpine can be isolated from this concentrate by liquid chromatography. It is eluded, first with benzene, and then with benzene/acetone (2 : 1), from a column of neutral aluminum oxide. The alkaloid is recrystallized from hot acetone and melts at 262 – 263 °C with decomposition.

Pharmacological Properties. Yohimbine is a local anaesthetic, reduces blood pressure, and increases depth and frequency of respiratory movements. It is known to be an adrenergic blocking agent. It has been used as an aphrodisiac. The diacetyl derivative is also an effective vasodilator. Reserpine restricts local arteries and reduces preservation of catecholamine and serotonin. Reserpine is a tranquilizer and is used to prevent aortic rupture in turkeys. It is an antihypertensive agent.

Therapeutic Use. Rescinamine: tranquilizer, antihypertensive agent, sympathicolytic.

Syrosingopine: antihypertensive agent.

Methoserpine: antihypertensive agent.

Deserpidine: tranquilizer.

Trade Names. Yohimbine: Yohimbin "Buchler", Yohimbine "Houde" (Lirca), Yohimbin-Spiegel (Kalichemie).

Reserpine: Eskaserp (Smith Kline & French), Rau-Sed (Squibb), Réserpine Chantereau, Reserpin (Leo), Réserpine Nativelle, Rivasin (Giuliani), Sandril (Lilly), Serpate (Vale), Reserpin (Hameln), Abicol (Boots), Seominal (Winthrop), Sedaraupin (Boehringer Mannheim), Serpasil (Ciba), Spansule (Smith Kline & French), Reserpoid (Upjohn), Rauvilid (Pharmacia), Apoplon (Daiichi), Resermin (Takeda), Toriserpin (Torii), Resera (Sanwa).

Rescinamine: Moderil (Pfizer), Rozex (Teisan), Apolon (Toyama), Ruconax (Sato), Paresinan (Wakamoto), Anaprel (Servier), Recinate (Ohta).

Methoserpine: Decaserpyl (Roussel).

Deserpidine: Harmonyl (Abbott), Deserpidine (Ono).

11.3.3.4. Sarpagine

Sarpagine was isolated from *Rauwolfia serpentina*. Its stereochemistry was assigned as **323** on the basis of spectroscopic evidence.

323 Sarpagine

11.3.3.5. Ajmaline

Ajmaline was found in the root of *Rauwolfia serpentina* to the extent of about 0.5 %. Its structure was determined by WOODWARD and ROBINSON [326]. The first total synthesis of ajmaline (**324**) was reported by MASAMUNE [327].

324 Ajmaline

Ajmaline (**324**) [*4360-12-7*], $C_{20}H_{26}N_2O_2$, M_r 326: prisms, adduct with 1 mol of methanol (from methanol), *mp* 158 – 160 °C, $[\alpha]_D^{18}$ + 131 ° (c = 0.4 g/100 ml in chloroform).

Pharmacological Properties. Ajmaline shows an anti-ephedrine activity and is used as an anti-arrhythmic drug, antihypertensive, and tranquilizer.

Therapeutic Use: antiarrhythmic agent.

Trade Names: Gilurytmal (Giuliani), Cardiorythmine 5 (Servier), Ritmos (Inverni Della Beffa), Raugallin (Chibe), Ajmal (Kanto Ishi), Ajmalin (Mochida), Ajsal (Teisan).

11.3.3.6. Picraline

Picraline (**325**) and related alkaloids were found in several *Alstonia* species. Their structures were

determined on the basis of spectroscopic evidence. Picralinal (**326**) has possible hypotensive and anticancer properties.

325 R = CH_2OAc Picraline **326** R = CHO Picralinal Ac = $COCH_3$

11.3.3.7. Vobasine

These alkaloids have a 2-acylindole skeleton in their structure. Dregamine (**328**) is a dihydro compound of vobasine (**327**). The conversion of the *N*-oxide of **327** and **328** into the ervatamine-type alkaloids was achieved in vitro. Therefore, the synthesis of dregamine reported by KUTNEY constitutes a formal synthesis of 20-*epi*-ervatamine (**329**) [328].

327 Vobasine

328 Dregamine

329 Ervatamine

11.3.3.8. Pleiocarpamine

Pleiocarpamine (**330**), isolated from *Pleiocarpamutica* Benth., is a C-20 indole alkaloid, which is converted into the isomeric epipleiocarpamine on treatment with strong bases. Subsequent reduction with lithium aluminum hydride and *N*-methylation with methyl iodide afforded C-mavacurine (**331**).

330 Pleiocarpamine

331 C-Mavacurine

11.3.3.9. Strychnine

Structure, Occurence, and Synthesis. Strychnine (**332**) is the most important of the *Strychnos* alkaloids. Its structure was initially determined by ROBINSON and WOODWARD and confirmed by X-ray analysis [329]. Total synthesis of strychnine was accomplished by WOODWARD, who employed a catechol cleavage reaction (Woodward fission) [330]. Strychnine was converted into caracurine VII (**334**), also isolated from *Strychnos toxifera,* by WIELAND and GUMLICH [331]. Investigation of biosynthesis of strychnine (**332**) revealed that geissoschizine and the Wieland-Gumlich aldehyde (**334**) were key precursors. The *N*-acetyl derivative of the Wieland-Gumlich aldehyde is diaboline. Aspidospermatidine (**336**) and condylocarpine (**337**) were also placed in this group because of their structural relationship to strychnine.

332 R^1 = H, R^2 = H Strychnine

334 R = H, Wieland-Gumlich aldehyde (Caracurine VII)

335 R = Ac Diaboline

336 Aspidospermatidine

337 Condylocarpine

Physical Properties.

Strychnine (**332**) [*57-24-9*], $C_{21}H_{22}N_2O_2$, M_r 334: colorless rhombohedrons (from ethanol), *mp* 268–290 °C (depends on heating rate), $[\alpha]_D$ − 145 ° (chloroform).

Brucine (**333**) [*357-57-3*], $C_{23}H_{26}N_2O_4$, M_r 394: colorless prisms (from ethanol/water), *mp* 178 °C, $[\alpha]_D$ − 127 ° (chloroform).

Wieland-Gumlich aldehyde (**334**) [*466-85-3*] $C_{19}H_{22}N_2O_2$, M_r 310: *mp* 213–214 °C decomp. (from acetone/methanol), $[\alpha]_D^{22}$ − 133.8 ° (c = 0.52 in methanol).

Diaboline (**335**) [*509-40-0*], $C_{21}H_{24}N_2O_3$, M_r 352: *mp* 187 °C (from ether), $[\alpha]_D^{22}$ + 37.8 ° (c = 1.72 in chloroform).

Preparation. Only strychnine is isolated on an industrial scale, and only strychnine and products obtainable from it are of practical importance.

Vomiting nuts (*Nux vomica*) are used as the starting material for the isolation of strychnine. The raw nuts contain 2–3 % alkaloids, of which approximately half is strychnine. The alkaloids are set free with calcium hydroxide, extracted continuously with benzene or toluene, and transferred from the organic phase to an aqueous sulfuric acid phase. Precipitation with soda solution gives a raw alkaloid mixture, from which pure strychnine is obtained by crystallization with 50 % ethanol and recrystallization. Brucine can be isolated from the mother liquors; colubrine and vomicine, from the final mother liquors.

Pharmacological Properties. Strychnine is a highly toxic alkaloid and affects the spinal cord to produce excessive reflex irritability. Lethal doses lead to the death of mammals by respiratory failure. In large doses, strychnine paralyzes the central nervous system, leading instantaneously to the death of mammals. It is used in medicine as a tonic and stimulant; however, its major use is as a vermin killer. MLD (minimum lethal dose) orally in rats: 5 mg/kg for strychnine.

Therapeutic Use. Strychnine: analeptic agent.

Brucine: analeptic agent.

Strychnic acid: depot analeptic agent.

338 Strychnic acid

Trade Names. Strychnine: Strychnine (Mallinckrodt, MSD), Strychnin. nitric. (Dr. Buchler), Strychnin Nitrate (Torii, Kyoritsu).

Strychnine dimethylarsinate: Strychnium Kadoylicum (Boehringer Ingelheim). *Strychnine Sulfate* (Lilly), *Strychnine Phosphate* (Smith Klein Fujisawa).

Brucine: Genostrychnin (Amido), Invocan (Pharm. Fabr. Hameln), Movellan (Asta).

Strychnic acid : Movellan (Asta).

11.3.3.10. Akuammicine

Akuammicine (**339**) is a minor constituent of *Picralima klaineana* Pierre and is chemically derived from strychnine [332].

339 Akuammicine

Physical Properties.

Akuammicine (**339**) [*639-43-0*], $C_{20}H_{22}N_2O_2$, M_r 322: *mp* 182 °C (from dilute ethanol), $[\alpha]_D^{16}$ − 745 ° (c = 0.994 in ethanol).

11.3.3.11. Ellipticine

Structure, Occurrence, and Synthesis. Ellipticine (**340**) [333] and olivacine (**341**) [334] lack the normal tryptamine unit in their fundamental structure; however, they are placed with the Aspidosperma alkaloids as they were found in *Aspidosperma* species. Interest in the synthesis of these alkaloids stems from their marked antitumor activity. The first synthesis of ellipticine (**340**) was achieved by WOODWARD [335]. Olivacine (**341**) was synthesized by several groups [336]. Uleine (**342**), apparicine (**343**), and vallesamine (**344**) also do not bear

a tryptamine unit as a distinguishable feature in their fundamental structure, but they are normally grouped under the *Aspidosperma* family since they occur in *Aspidosperma* species. Synthesis of uleine (**342**) was achieved stereoselectively by BÜCHI [337], whereas KAMETANI [338] published the efficient synthesis of several members of the dasycarpidone-uleine series.

340 Ellipticine

341 Olivacine

343 Apparicine

344 Vallesamine

Physical Properties.

Ellipticine (**340**) [*519-23-3*], $C_{17}H_{14}N_2$, M_r 246: *mp* 311 – 315 °C decomp. (from ethyl acetate).

Olivacine (**341**) [*484-49-1*], $C_{17}H_{14}N_2$, M_r 246: *mp* 317 – 325 °C (from methanol).

Pharmacological Properties. Ellipticine and olivacine exhibited antitumor activity in appropriate biological evaluation in various tumor systems. LD_{50} i.v. in mice: 19.5 – 22.4 mg/kg for ellipticine.

11.3.3.12. Aspidospermine

Aspidosperma alkaloids are derived biosynthetically from tryptophan and secologanin via geissoschizine, stemmadenine, and dehydrosecodine. Many syntheses and synthetic approaches were attempted along this pathway, which involves an intramolecular Diels-Alder reaction of dehydrosecodine. STORK's first synthesis of aspidospermine (**345**) utilized an enamine annelation reaction and Fischer indole cyclization of a phenylhydrazone derivative [339]. The synthesis of vindoline (**348**), a major component of *Vinca rosea,* was accomplished by BÜCHI [340] and KUTNEY [341], and this alkaloid is an important compound because it is the precursor of dimeric indole alkaloids possessing antitumor activity. Treatment of vincadifformine, obtained from tabersonine (**347**) by partial reduction with formic acid and formamide followed by reduction, afforded vincadine and quebrachamine (**346**).

345 Aspidospermine

Quebrachamine (**346**) [*4850-21-9*], $C_{19}H_{26}N_2$, M_r 282: *mp* 145 – 147 °C, $[\alpha]_D^{20}$ – 109 to – 110 ° (acetone).

Vindoline (**348**) [*2182-14-1*], $C_{25}H_{32}N_2O_6$, M_r 456: *mp* 164 – 165 °C for needles (from acetone + petroleum ether), *mp* 174 – 175 °C for prisms, $[\alpha]_D^{20}$ – 18 ° (chloroform).

11.3.3.13. Aspidofractine

The hexacyclic alkaloids are considered to be derived biogenetically from aspidospermine-type pentacylic alkaloids. In fact, minovincine (**353**) was chemically converted into aspidofractinine (**352**) by treatment with hydrochloric acid and subsequent reduction [377]. The degradation of

kopsine (**351**) to aspidofractinine (**352**) indicated its absolute configuration, [343].

349 R = CHO Aspidofractine

11.3.3.14. Eburnamine

Eburnamine-type alkaloids are the rearrangement products of aspidospermine-type compounds. 1,2-Dehydroaspidospermidine *N*-oxide (**358**) was converted into eburnamine (**354**) by treatment with triphenylphosphine in aqueous acetic acid [344]. Moreover, vincamine (**355**) was formed from tabersonine in several steps. (−)-Eburnamonine (**356**) was also prepared from vincamine (**355**). Schizophylline (**357**) is also grouped under *Aspidosperma* family on the basis of its natural source; however, its biosynthetic pathway has not yet been determined.

Physical Properties.
Vincamine (**355**) [*1617-90-9*], $C_{21}H_{26}N_2O_3$, M_r 354: *mp* 232–233 °C (from acetone or methanol), $[\alpha]_D^{23}$ +41° (pyridine).
Eburnamonine (**356**) [*474-00-0*], $C_{19}H_{22}N_2O$, M_r 294: *mp* 174 °C, $[\alpha]_D^{25}$ +89° (chloroform).

357 Schizophylline

358

11.3.3.15. Catharanthine

Catharanthine (**359**) is a minor constituent of *Vinca rosea* [345] and is derived from dehydrosecodine by an intramolecular cyclization. This alkaloid is important as the upper half of the dimeric indole alkaloids vinblastine and vincristine.

359 (+)-Catharanthine

Physical Properties.
Catharanthine (**359**) [*2468-21-5*], $C_{21}H_{24}N_2O_2$, M_r 336: *mp* 126–128 °C (from methanol), $[\alpha]_D^{27}$ +29.8° (chloroform).

11.3.3.16. Ibogamine

Ibogamine (**360**) and ibogaine (**361**) were isolated from *Tabernanthe iboga,* and their structures were determined by X-ray analysis [346] and total synthesis [347].

360 R = H (−)-Ibogamine **361** R = OCH_3 (−)-Ibogaine

It is reported that ibogaine inhibits the action of serum cholinesterase.

Physical Properties.
Ibogaine (**361**) [*83-74-9*], $C_{20}H_{26}N_2O$, M_r 310: *mp* 152–153 °C (from ethanol), $[\alpha]_D^{20}$ −53 ° (95 % ethanol).

11.3.3.17. Cleavamine

Cleavamine (**362**) was derived from catharanthine (**359**) by treatment with acid. Its stereochemistry was confirmed by X-ray analysis [348]. Cleavamine was chemically related to ibogamine (**360**). Oxidation of 16α-carbomethoxycleavamine with mercuric acetate afforded two products, one of which was identical with the dehydration product of pandoline (**364**) except for its optical rotation. Dihydrocleavamine (**363**) was also converted into pseudovincadifformine (**368**) by oxidation with mercuric acetate.

Two new indole alkaloids, ibophyllidine (**366**) and iboxyphylline (**367**), were obtained from *Tabernanthe iboga.* Their structures were assigned as **366** and **367** on the basis of spectroscopic evidence. These two alkaloids were suggested to be derived from pandoline (**364**) biosynthetically. The conversion of pandoline (**364**) into velbanamine (**369**) was achieved by catalytic hydrogenation in trifluoroacetic acid followed by acid catalyzed decarboxylation.

11.3.3.18. Andranginine

Andranginine (**370**), isolated from *Craspidospermum verticillatum*, was synthesized from 19-iodotabersonine (**371**) via the olefin **372** by dehydrohalogenation followed by heating in methanol, to confirm its biosynthetic pathway.

11.3.4. Bis-Indole Alkaloids

Strucure and Synthesis. Vinblastine (**373**) is an important alkaloid because of its biological activity. Vinblastine seems to be derived biosynthetically from vindoline and catharanthine on the basis of tracer experiments with a cell-free enzyme system [349]. Synthesis of vinblastine was accomplished by POTIER, who employed a modified Polonovski reaction to control the stereochemistry at the 18-position [350]: Catharanthine *N*-oxide was treated with trifluoroacetic anhydride in the presence of vindoline to give dehydrovinblastine (**375**). Catalytic reduction afforded deoxyvinblastine. Repeated Polonovski reaction followed by introduction of a hydroxyl group completed the synthesis of vinblastine. Vincristine (**374**) was synthesized from vinblastine (**373**) by selective oxidation of the *N*-methyl

function of vindoline with the Jones reagent at low temperature. Villalstonine (**376**) is obtained from several *Alstonia* species.

370 Andranginine

371

372

Physical Properties.

Vinblastine (Vincaleukoblastine) (**373**) [*865-21-4*], $C_{46}H_{58}N_4O_9$, M_r 831: *mp* 211 – 216 °C decomp. (from methanol), $[\alpha]_D^{26}$ + 42 ° (chloroform).

Vincristine (22-oxovincaleukoblastine, Leurocristine) (**374**) [*57-22-7*], $C_{46}H_{56}N_4O_{10}$, M_r 844: *mp* 218 – 220 °C decomp. (from methanol), $[\alpha]_D^{26}$ + 17.0 ° (chloroform).

Preparation. Vinblastine and Vincristine occur in *Catharanthus roseus* (L). The plant contains only very small amounts of vinblastine and vincristine, and their isolation is correspondingly difficult [351]. First the alkaloids present are separated by extraction into alkaloid tartrate soluble in benzene and alkaloid tartrates insoluble in benzene. Vinblastine and vincristine belong to the first group. They then are separated by chromatography on aluminum oxide deactivated with acetic acid.

Ac = $COCH_3$
373 R = CH_3 Vinblastine
374 R = CHO Vincristine

375 Dehydrovinblastine

376 Villalstonine

Pharmacological Properties. Vinblastine (**373**) exhibits an antitumor activity and is also active against certain leukaemias. Vincristine (**374**) is active against leukaemias and causes either thrombocytosis with no effect upon the leucocytes or thrombocytopenia accompanied by peucopenia in rats. LD_{50} i.v. in mice: 17 mg/kg for vinblastine. LD_{50} i.p. in mice: 5.2 mg/kg for vincristine.

Therapeutic Use. Vinblastine: Hodgkin's disease and other lymphomas, chorioepithelial carcinoma.

Vincristine: childhood leukaemia.

Trade Names. Vinblastine: Velban, Velbe (Lilly), Exal (Shionogi), Vinblastin (Kyorin).

Vincristine: Oncovin (Lilly), Kyocristine (Kyorin), Vincosid (Leo).

11.3.5. Biogenetically Related Quinoline Alkaloids

Structure and Synthesis. These alkaloids are biogenetically derived from appropriate indole alkaloids. Chemical correlation between cinchona alkaloids and indole alkaloids, of the corynanthe group, were carried out based on the consideration of their biosynthetic pathway. KAMETANI reported the transformation of an indole ring into a quinoline ring involving a photooxygenation reaction [352]. The

use of this reaction also led to the biomimetic synthesis of camptothecine (**377**). Streptonigrin was produced by *Streptomyces flocculus,* and its structure was determined as **381** [353]. Total synthesis of streptonigrin was reported by Weinreb and Kende [354]. The structure of meloscine (**382**), characterized by a unique framework, was confirmed by X-ray analysis [355].

377 Camptothecine

378 $R^1 = OCH_3$, $R^2 = H$, $R^3 = OH$ (−)-Quinine
379 $R^1 = H$, $R^3 = H$, $R^2 = OH$ (+)-Cinchonine
380 $R^1 = OCH_3$, $R^2 = OH$, $R^3 = H$ (+)-Quinidine

381 Streptonigrin

382 (+)-Meloscine

Physical Properties.

Camptothecine (**377**) [*7689-03-4*], $C_{20}H_{16}N_2O_4$, M_r 348: *mp* 264 – 267 °C decomp. (from methanol + acetonitrile), $[\alpha]_D^{25}$ + 31.3 ° (chloroform – methanol).

Quinine (**378**) [*130-95-0*], $C_{20}H_{24}N_2O_2$, M_r 324: *mp* 174.4 – 175.5 °C, $[\alpha]_D$ − 158 ° (ethanol). $C_{20}H_{24}N_2O_2 \cdot H_2O$ (from water): *mp* 57 °C.

Cinchonine (**379**) [*118-10-5*], $C_{19}H_{22}N_2O$, M_r 294: *mp* about 265 °C (from ethanol or ether), begins to sublime at 220 °C, $[\alpha]_D$ + 229 ° (ethanol).

Quinidine (**380**) [*56-54-2*], $C_{20}H_{24}N_2O_2$, M_r 324: *mp* 173.5 °C (from ether, ethanol, or water), $[\alpha]_D^{15}$ + 334.1 ° (in 0.1 N sulfuric acid).

Streptonigrin (**381**) [*3930-19-6*] $C_{25}H_{22}N_4O_8$, M_r 506: *mp* 275 °C decomp. (acetone or dioxane).

Dihydroquinidine, $C_{20}H_{26}N_2O_2$, M_r 326: *mp* 169.5 °C (from ether or ethanol), $[\alpha]_D^{15}$ − 299 ° (c = 0.025 M in 0.1 N sulfuric acid).

Preparation of Quinine. The finely powdered *cinchona* peel is treated with dissolved lime and 5 % sodium hydroxide solution and then extracted with aromatic hydrocarbons at 60 °C. The raw alkaloid is removed from the organic solvent by shaking with dilute sulfuric acid. The concentrated sulfuric acid-raw alkaloid solution is heated to its boiling point, and 10 % sodium hydroxide solution added until the solution is almost neutralized. Depending on the pH, the mono- or bisulfate crystallizes on cooling. Quinine is purified by recrystallization of either the mono- or bisulfate.

Pharmacological Properties. Quinine and cinchonine exhibit activity against *Plasmodium* species and are used as antimalarials. Quinine and its salts show bitter stomachic, analgesic, and antipyretic activities, whereas quinidine shows an antiarrhythmic activity. Camptothecin is suggested to have antitumor and antileukaemia activity. It prolonged life as much as 100 % when used in treatment of leukaemia L 1210 in mice. It was subjected to phase II clinical studies with gastrointestinal cancer; however, the study had to be dropped because of high toxicity. 10-Hydroxycamptothecin is expected to be more promising in treatment of certain tumors. Streptonigrin also exhibits antineoplasmic activity, but it causes severe and prolonged bone-marrow depression.

Therapeutic Use. Quinidine and Dihydroquinidine: antiarrhythmic agent.

Trade Names. Quinine-carboxy-3-salicylate: Hivernine (Vaillant), *Ethyl carbonate:* Chininum aethylcarbonicum (Buchler). *Quinine*

sulfate: Coco-Quinin (Lilly), Quine (Rowell). *Quinine hydrochloride:* Kinurea Terrial "H" (Dr. Dumesny). *Dihydrochloride:* Chininum dihydrochloricum (Buchler).

Quinidine Gluconate: Duraquin (Parke Davis). *Quinidine phenyl-S-ethyl-5-barbiturate:* Natisedine (Nativelle). *Quinidine-polygalacturonate:* Galactoquin (Mundipharma), Naticardina (Chinoin). *Quinidine sulfate:* Cin-Quin (Rowell), Optochinidin (Boehringer Mannheim), Quinidex LA (Robins), Novoquinidin (Novopharm), Systodin (Buchler). *Quinidine hydrogensulfate:* Kiditard (Delandale), Kinidin Durules (Astra), Optochinidin retard (Boehringer Mannheim), Quinidurule (Searle-Astra), Quinidex Extentabs (Robins).

Dihydroquinidine: Hydroquinidine "Houde", Serecor (Houde).

12. Lycopodium Alkaloids

Structure, Occurrence, and Synthesis. Since the structure determination of annotinine by WIESNER in 1957 [356], the chemistry of lycopodium alkaloids has progressed rapidly. The typical alkaloid found in the *Lycopodium* family is lycopodine. Its structure was assigned as **383** by MANSKE [357]. Several alkaloids of this group have been chemically related. For example, lycodine (**386**) was synthesized from lycopodine in four steps [358]. The structures of annotine (**384**) and serratinine (**385**) were confirmed by X-ray analysis [359]. Selagine [360], isolated from *Lycopodium selago,* was assigned as **387** on the basis of spectra and chemical degradation. Total synthesis of the *Lycopodium* alkaloids lycopodine, lycodine, and lycodoline was accomplished by HEATHCOCK [361].

383 Lycopodine

384 Annotine

385 Serratinine

386 Lycodine

387 Selagine

388 Cernuine

389 Serratinidine
Ac = $COCH_3$

Physical Properties.

Lycopodine (**383**) [*466-61-5*], $C_{16}H_{25}NO$, M_r 247: *mp* 114 – 115 °C, $[\alpha]_D$ – 24 ° (ethanol).

Lycodine (**386**) [*20316-18-1*], $C_{16}H_{22}N_2$, M_r 242: *mp* 118 – 119 °C, $[\alpha]_D$ – 10 ° (ethanol).

Selagine (**387**) [*116-28-9*], $C_{15}H_{18}N_2O$, M_r 242: *mp* 224 – 226 °C, $[\alpha]_D^{25}$ – 99 ° (methanol).

Pharmacological Properties. The *Lycopodium* alkaloids are moderately toxic. They seem to show a variety of activities including pressor activity, stimulation and contraction of the uterus, and paralysis. However, none of these have been useful in medicine.

13. Terpene Alkaloids

13.1. Monoterpene Alkaloids

Structure. The monoterpene family of alkaloids arises in the condensation of iridoids or secoiridoids with ammonia. Gentianine (**390**) is well known as the monoterpene pyridine alkaloid and is the most widely distributed. Synthesis of gentianine (**390**) was achieved by GOVINDACHARI [362]. Tecomine, isolated from *Tecoma* species, was assigned as **391** by JONES [363]. A synthesis of tecomine (**391**) was achieved by HANAOKA [364].

390 Gentianine

391 Tecomine (Tecomanine)

392 Dendrobine

393 Fabianine

394 (−)-Patchoulipyridine

395 (−)-Nupharamine

Physical Properties.

Gentianine (**390**) [*439-89-4*], $C_{10}H_9NO_2$, M_r 175: *mp* 82 – 83 °C (from ether).

Tecomanine (**391**) [*6878-83-7*], $C_{11}H_{17}NO$, M_r 179: *bp* 125 °C (at 0.01 kPa), $[\alpha]_D^{24}$ − 175 ° (chloroform).

Pharmacological Properties. Gentianine has a low toxicity and stimulates the central nervous system. In large doses it can paralyze. Gentianine also may exert anti-inflammatory, hypotensive, and muscular-relaxant activities. The leaves of various *Tecoma* species are used in Mexico by natives for the control of diabetes. Tecomine citrate shows hypoglycemic activity.

13.2. Sesquiterpene Alkaloids

Structure and Occurrence. Dendrobine (**392**) was isolated from genus *Dendrobium.* Its structure was deduced to be **392** on the basis of spectroscopic evidence and chemical correlations [365]. The biosynthesis of dendrobine is consistant with its derivation from mevalonate via farnesol, germacrane, and cadalane skeletons. Synthesis of **392** was first accomplished by INUBUSHI [366]. Furthermore, formal total synthesis of (−)-dendrobine was reported by SHIBASAKI [367]. Fabianine (**393**) and patchoulipyridine (**394**) were derived biosynthetically from the sesquiterpenes. (−)-Patchoulipyridine (**394**) was made from patchouli alcohol [368], [369]. (−)-Nupharamine (**395**) and other related bases are distributed in *Nuphar* species. The synthesis of (±)-fabianine (**393**) and (−)-patchoulipyridine (**394**) has been reported [370], [371].

Physical Properties.

Dendrobine (**392**) [*2115-91-5*], $C_{16}H_{25}NO_2$, M_r 263: *fp* 134 °C (sublime), $[\alpha]_D^{16}$ − 51.5 ° (ethanol).

Fabianine (**393**) [*6871-51-8*], $C_{14}H_{21}NO$, M_r 219: *bp* 74 °C (at 6.7 Pa), $[\alpha]_D < 1$ °.

Patchoulipyridine (**394**) [*6517-97-1*], $C_{15}H_{21}N$, M_r 215: *bp* ca. 80 °C (at 13.3 Pa), *mp* 24 – 26.5 °C (white waxy needles), $[\alpha]_D^{28}$ − 31.3 ° (ethanol).

(−)-*Nupharamine* (**395**) [*17812-38-3*], $C_{15}H_{25}NO_2$, M_r 251: *bp* 130 – 134 °C, $[\alpha]_D^{22}$ − 35.04 ° (chloroform).

Pharmacology. Dendrobine reduces blood pressure and depresses respiration. In large doses it also diminishes cardiac activity and brings about moderate hyperglycemia. It shows weak analgesic and antipyretic activities.

409 Heteratisine

13.3. Diterpene Alkaloids

Structure, Occurrence, and Synthesis. Diterpene alkaloids, isolated from plants of the *Delphinium* and *Aconitum* genera (Ranunculaceae) and *Inula royleana* (Compositae), are of interest because of their physiological activities and their unique carbon framework. These alkaloids are possibly derived biogenetically from tetracyclic or pentacyclic diterpenes in which the nitrogen atom of β-aminoethanol, methylamine, or ethylamine forms a substituted piperidine ring.

Atisine (**396**) is the major constituent of several *Aconitum* species. The conversion of the atisane skeleton to the aconitine (**402**) skeleton was achieved [372] along the commonly accepted biogenetic route for aconitine-type alkaloids. Veatchine (**397**) and garryine (**399**) have a kaurene skeleton, and they are the positional isomers of an aminoethanol unit. Synthesis of these last three alkaloids was accomplished by NAGATA [373], whereas the efficient synthesis of the key intermediate for these alkaloids was achieved by KAMETANI [374]. Delphinine (**400**), chasmanine (**401**), and aconitine (**402**) are grouped into the aconitine type, which has no oxygen functional group or substituent at the C-7 position, whereas the lycoctonine type bears oxygen functional groups at the C-6 and C-7 positions. The structure of the alkaloids (**404**) – (**408**) resembles that of atisine (**396**), and these are placed in the atisane group. The alkaloids in the heteratisine (**409**) group always possess a lactone moiety. New alkaloids have been found in *Delphinium* species [375], [376].

Physical Properties.

Atisine (**396**) [*466-43-3*], $C_{22}H_{33}NO_2$, M_r 343: *mp* 57 – 60 °C. Hydrochloride: *mp* 311 – 312 °C decomp. (from dilute ethanol), $[\alpha]_D^{25}$ + 28 ° (ethanol).

Veatchine (**397**) [*76-53-9*], $C_{22}H_{33}NO_2$, M_r 343: *mp* 119 – 120 °C (from dilute acetone), $[\alpha]_D^{27.5}$ – 69.01 ° (ethanol).

Garryine (**399**) [*561-51-3*], $C_{22}H_{33}NO_2$, M_r 343: *mp* 74 – 82 °C (from dilute acetone), $[\alpha]_D^{27.5}$ – 84.23 ° (ethanol).

Delphinine (**400**) [*561-07-9*], $C_{33}H_{45}NO_9$, M_r 599: *mp* 197.5 – 199 °C (from ethanol), $[\alpha]_D^{20}$ + 25 ° (ethanol).

Aconitine (**402**) [*302-27-2*], $C_{34}H_{47}NO_{11}$, M_r 645: mp 204 °C, $[\alpha]_D$ + 17.3 ° (chloroform).

Lycoctonine (**403**) [*26000-17-9*], $C_{25}H_{41}NO_7$, M_r 467: *mp* 143 °C, $[\alpha]_D^{20}$ + 53 ° (ethanol).

Ajaconine (**404**) [*545-61-9*], $C_{22}H_{33}NO_3$, M_r 359: *mp* 172 °C (from dilute ethanol), $[\alpha]_D^{18}$ – 119 ° (ethanol).

Pharmacological Properties. Aconitine, delphinine, and related alkaloids irritate the skin and cause death due to respiratory failure and cardiac and vasomotor damage. Atisine is relatively nontoxic in comparison to aconitine.

14. Steroidal Alkaloids

14.1. Alkaloids of the Apocynaceae

Conessine was found in several *Holarrhena* species. Its structure was deduced to be **410** by chemical conversion to 3β-acetoxy-20α-aminopregn-5-ene [377]. Irehdiamine A (**411**), was isolated from *Funtumia elastica* [378]. The structure of conanine (**412**) was confirmed by X-ray analysis of its *N*-oxide derivative [379]. A formal total synthesis of (+)-connecine (**410**) was reported by MEYERS [380].

Conessine (**410**) $C_{24}H_{40}N_2$, M_r 356: *mp* 127 – 128.5 °C (from acetone), $[\alpha]_D^{20}$ +25.3° (ethanol).

Although conessine produces local anaesthesia, it causes local necrosis on subcutaneous injection. This alkaloid inhibits the growth of *Mycobacterium tuberculosis* in vitro. Conessine is used mainly as a remedy for amoebic dysentery.

410 (+)-Conessine

411 Irehdiamine A

412 Conanine

14.2. Buxus Alkaloids

The buxus family of alkaloids bears a cyclopropane ring on the B-ring or a seven-membered B-ring. Cyclobuxine D (**413**), isolated from *Buxus* species, was chemically correlated to cycloeucalenol (**414**) [381]. The structure of buxozine C (**415**) was determined in spectroscopic studies [382].

Cyclobuxine D (**413**) $C_{25}H_{42}N_2O$, M_r 386: *mp* 245 – 247 °C (decomp.), $[\alpha]_D^{23}$ +98° (chloroform).

413 Cyclobuxine D

414 Cycloeucalenol

415 Buxozine C

14.3. Alkaloids of the Asclepiadaceae

Stephanthraniline A (**416**), isolated from *Stephanotis japonica,* has an *N*-methylanthraniloyl ester moiety [383]. Other steroidal alkaloids are found in *Stephanotis* species [384]. Its

base-catalyzed hydrolysis afforded the known pregnane derivative sarcostin.

416 Stephanthraniline A

Stephanthraniline A (**416**) [*65429-40-5*] $C_{31}H_{43}O_8$, M_r 557: *mp* 170–173 °C (from acetone–hexane), $[\alpha]_D$ +17.9 ° (chloroform).

14.4. Solanum Alkaloids

Solasodine (**417**) is distributed in *Solanum* species. It is becoming an important starting material for the synthesis of steroids in the pharmaceutical industry [385]. Some of the *Solanum* alkaloids exhibit antibiotic effects on certain fungi and bacteria.

417 Solasodine

Solasodine (**417**) [*126-17-0*], $C_{27}H_{43}NO_2$, M_r 413: *mp* 200–202 °C (from methanol), $[\alpha]_D^{25}$ −98 ° (methanol), $[\alpha]_D$ −113 ° (chloroform).

Solasodine was shown to possess cardiotonic and antiphlogistic effects on mice and some effects on vascular permeability and the central nervous system.

14.5. Veratrum and Fritillaria Alkaloids

Jervine (**418**) and verticine (**419**) have C-nor-D homosteroidal linkage and were synthesized from hecogenin [386], [387].

418 (−)-Jervine

419 Verticine

Jervine (**418**) [*469-59-0*], $C_{27}H_{39}NO_3$, M_r 425: *mp* 243.5–244.5 °C /378.(from dilute methanol), $[\alpha]_D^{20}$ −150 ° (ethanol), $[\alpha]_D^{20}$ −167.6 ° (chloroform).

Verticine (**419**) [*23496-41-5*], $C_{27}H_{45}NO_3$, M_r 431: *mp* 223–224 °C (from ethanol), $[\alpha]_D^{16}$ −19.4 ° (ethanol), $[\alpha]_D^{17}$ −20 ° (chloroform).

Jervine was suggested to cause antiaccelerator cardiac action. In large doses it produces vasodilatation and a fall in blood pressure.

14.6. Phyllobates Alkaloids

Batrachotoxin (**420**) and batrachotixin A (**421**) were isolated from the skin of neotropical poison-dart frogs, genus *Phyllobates* [388], and their structures were established by spectroscopic and chemical studies. The former alkaloid is the most potent cardiotoxin known. The absolute configuration of batrachotoxinin A was determined by X-ray analysis [389]. The LD_{50} value of batrachotoxin is 2 µg/kg (s.c. in mice), while that of batrachotoxinin A is 1000 µg/kg (s.c. in mice). Toxic effect is caused by selective and irreversible increase in permeability of membranes to Na^+ ions. Several reports on synthetic studies have appeared [390–392].

420 Batrachotoxin

421 Batrachotoxinin A

Physical Properties

Batrachotixin (**420**) [*23509-16-2*], $C_{31}H_{42}N_2O_6$, M_r 538: $[\alpha]_D^{24}$ $-5°$ to $-10°$; $[\alpha]_{300}^{24}$ $-260°$ ($c = 0.23$ in methanol).

15. Miscellaneous Alkaloids

15.1. Muscarine Alkaloids

Muscarine (**422**) is found in the fly mushroom, *Amanita muscaria,* and is a hallucinogenic choline analogue. Its structure was confirmed by X-ray analysis [393]. Muscarine is a parasympathomimetic drug. L-Arabinose was converted into muscarine by EUGSTER [394]. Total synthesis of (+)-muscarine was accomplished by ADAMS [395].

422 (+)-Muscarine

Muscarine (**422**) [*300-54-9*], $C_9H_{20}ClNO_2$ M_r 210: *mp* 180 – 181 °C (from ethanol), $[\alpha]_D^{25}$ +8.1° (ethanol). LD_{50} i.v. in mice: 0.23 mg/kg.

15.2. Imidazole Alkaloids

Anantine (**423**) is derived from cinnamic acid and histamine, which arises from histidine by decarboxylation. Histamine (**425**) occurs widely in nature as a result of putrefactive processes. The flavoprotein diamine oxidase converts histamine to the aldehyde and ammonia. Its phosphate is used as a diagnostic indicator for gastric secretion or pheochromocytoma. Anantine and related alkaloids were also reported [396]. Furthermore, the synthesis of (±)-anantine and (±)-isoanantine was achieved by NINOMIYA [397].

(S)-(E)-(−)-Anantine (**423**) [*50656-82-1*], $C_{15}H_{15}N_3O$, M_r 253: *fp* 204 °C, $[\alpha]_D$ $-549°$.

(S)-(E)-(−)-Isoanantine (**424**), $C_{15}H_{15}N_3O$, M_r 253: *fp* 190 °C (from acetone), $[\alpha]_D$ $-347°$.

Histamine (**425**) [*51-45-6*], $C_5H_9N_3$, M_r 111: *mp* 83 – 84 °C (from chloroform), *bp* 209 – 210 °C (at 2.4 kPa). LD_{50} i.p. in mice: 2020 mg/kg.

423 Anantine

425 Histamine

424 Isonatine

15.3. Polyamine Alkaloids

The family of polyamine alkaloids exhibits a variety of biological effects: antiviral, antitumor, and blood-pressure depressing activities. Maytansine is isolated from *Maytenus ovatus* Loes. Its structure was assigned as **426** by KUPCHAN [398]. Maytansine shows cytotoxic action, and it is expected to be an anticancer agent. The synthesis of (−)-maytansine and (−)-maytansinol was reported by COREY [399] and ISOBE [400]. The chemistry of spermine and spermidine alkaloids such as codonocarpine (**427**) and lunarine (**429**) is reviewed in [401]. Also isocodonocarpine (**428**) was isolated from the root bark of *Capparis decidua* [402]. The synthesis of condocarpine and (±)-lunarine was achieved by NAGAO [403], [404].

426 Maytansine

427 Codonocarpine

428 Iscadonocarpine

429 (+)-Lunarine

Maytansine (**426**) [*35846-53-8*], $C_{34}H_{46}ClN_3O_{10}$, M_r 692: *mp* 171 – 172 °C, $[\alpha]_D^{26}$ – 145 ° (chloroform).

(E,E)-codonocarpine (**427**) [*33442-48-7*], $C_{26}H_{31}N_3O_5$, M_r 465: *mp* 187 °C.

(+)-*Lunarine* (**429**) [*24185-51-1*], $C_{25}H_{31}N_3O_4$, M_r 437: *fp* 238 – 240 °C, $[\alpha]_D$ + 344 ° (ethanol).

15.4. Securinine Alkaloids

Securinine (**430**) is isolated from *Securinega suffructicosa* Rehd. Its structure was confirmed by X-ray analysis [405]. A report on stereoisomers of securine has appeared [406]. A synthesis was reported by Horii [407]. (–)-Securinine and its derivatives were synthesized by Wanner [408].

430 Securinine

Securinine (**430**) [*5610-40-2*], $C_{13}H_{15}NO_2$, M_r 217: *mp* 142 – 143 °C (from ethanol), $[\alpha]_D^{20}$ – 1042 ° (ethanol).

15.5. Tetrodotoxin

Tetrodotoxin (**431**) is identical with tarichatoxin, the poison of the California salamander *Taricha torosa* [409]. Tetrodotoxin is obtained from the ovaries of suitable fish after precipitating the protein by chromatography on active charcoal. Usually, 8 – 9 g of pure tetrodotoxin are obtained from 1000 g of roe. The structure of the compound was established by chemical, spectroscopic, and X-ray investigations. *rac*-Tetrodotoxin was synthesized [410]. The synthesis of optically active tetrodotoxine is reviewed in [411]. Tetrodotoxin is extremely poisonous, having a LD_{50} value with mice of 8 – 10 µg/kg. Consumption of poisonous fish causes paralysis of the respiratory center and respiratory muscles, leading to paresthesia, motor paralysis, and after 6 – 8 h death. Tetrodotoxin acts on the cell membranes such that the flow of Na^+ ions into the cells is hindered.

Tetrodotoxin (**431**) [*4368-28-9*], $C_{11}H_{17}N_3O_8$, M_r 319: *mp* > 200 °C, $[\alpha]_D^{25}$ – 8.64 ° (dilute acetic cid).

431 Tetrodotoxin

15.6. Aaptamine and Related Alkaloids

Aaptamine (**432**), demethylaaptamine (**433**), and demethyloxyaaptamine (**434**) were isolated from the marine sponge *Aaptos aap-*

tos [412]. The structures, with a new heterocylic system, were determined from spectroscopic evidence and by chemical degradation, and the biological activity of the alkaloids was evaluated. Aaptamine possesses potent α-adrenorecepter blocking activity on vascular smooth muscle. Demethyloxyaaptamine is cytotoxic against Hela cells (ED_{50} 0.87 µg/mL) and has potent antimicrobial activities against gram-positive and -negative bacteria such as *Staphylococcus aureus* [minimum inhibitory concentration (MIC) 3.13 mg/mL], *Bacillus subtilis* (MIC 6.25 mg/mL) and *protecus vulgaris* (MIC 12.5 mg/mL). The biological activity of **432** is weaker (about half) than that of **434**. Several reports concerned with total syntheses of aaptamine have appeared [413–421]. A synthesis of demethyloxyaaptamine was also reported [414].

432 R = CH_3 Aaptamine
433 R = H Demethylaaptamine

434 Demethyloxyaaptamine

Physical Properties.

Aaptamine (**432**) [*85547-22-4*], $C_{13}H_{12}N_2O_2$, M_r 228: *mp* 110 – 113 °C (hydrochloride).

Demethylaaptamine (**433**) [*88839-98-9*], $C_{12}H_{10}N_2O_2$, M_r 214: *mp* 248 – 251 °C (hydrochloride).

Demethyloxyaaptamine (**434**) [*88839-99-0*], $C_{12}H_8N_2O_2$, M_r 212: *mp* 210 – 212 °C (hydrochloride).

15.7. Eudistomidins

The alkaloids possessing a β-carboline skeleton eudistomidin A – F (**435** – **440**) were isolated from the Okinawan tunicate *Eudistoma glaucus* [422]. The structures were determined on the basis of spectroscopic evidence. The stereochemistry of eudistomidin F was not established.

435 Eudistomidin A

436 Eudistomidin B

437 Eudistomidin C

438 Eudistomidin D

439 Eudistomidin E

440 Eudistomidin F

Physical Properties.

Eudistomidin A (**435**) [*102673-53-0*], $C_{15}H_{12}BrN_3O$, M_r 330: *mp* 225 – 230 °C .

Eudistomidin B (**436**) [*125443-66-5*], $C_{21}H_{24}BrN_3O$, M_r 398: *mp* 81 – 83 °C, $[\alpha]_D^{22}$ – 54 °C (methanol), $[\alpha]_D$ – 76.4 °C (chloroform).

Eudistomidin C (**437**) [*125422-17-5*], $C_{15}H_{16}BrN_3OS$, M_r 366: *mp* 120 – 122 °C, $[\alpha]_D$ + 15.6 °C (methanol).

Eudistomidin D (**438**) [*125422-19-7*], $C_{12}H_9BrN_2O$, M_r 277: *mp* 180 °C.

Eudistomidin E (**439**) [*136094-35-4*], $C_{16}H_{16}BrN_3O_2S$, M_r 394: amorphous solid, $[\alpha]_D$ +19 °C (methanol)).

Eudistomidin F (**440**) [*136094-36-5*], $C_{16}H_{16}BrN_3OS$, M_r 378: amorphous solid, $[\alpha]_D$ +16 °C (methanol)).

Pharmacological Properties. Eudistomidin A is the first inhibitor of calmodulin-activated brain phosphodiesterase (2×10^{-5} mol/L) of marine origin. Eudistomidins B–D exhibit potent cytotoxic activity against murine leukemia L1210 (IC_{50} 3.4 µg/mL for B, 0.36 µg/mL for C, and 2.4 µg/mL for D) and L1210 (IC_{50} 3.1 µg/mL for B, 0.42 µg/mL for C, and 18 µg/mL for D). Eudistomidin B also activates rabbit heart muscle actomyosin ATPase (93 % at 3×10^{-5} mol/L). Eudistomidin C exhibits cytotoxic and calmodulin antagonistic activity ($IC_{50} = 3 \times 10^{-5}$ mol/L). Eudistomidin D exhibits cytotoxic activity and induces Ca^{2+} release from the sarcoplasmic reticulum about ten times more potently than caffein.

441 Manzamine A

442 Manzamine B

443 Manzamine C

15.8. Manzamines

Manzamines A–C (**441**)–(**443**) were isolated from the Okinawan marine sponges *Haliclona* sp. and *Pellina* sp. The structures were determined on the basis of spectroscopic evidence and X-ray analysis [423]. Manzamine A exhibits antitumor activity against P-388 leukemia cells (IC_{50} 0.07 µg/mL). IC_{50} 6 µg/mL for mansamine B, 3 µg/mL for manzamine C.

Physical Properties.

Manzamine A (**441**) [*104196-68-1*], $C_{36}H_{44}N_4O$, M_r 548: *mp* >240 °C, $[\alpha]_D$ +50 °C (chloroform).

Manzamine B (**442**) [*112663-92-0*], $C_{36}H_{44}N_4O$, M_r 550: *mp* 198–203 °C, $[\alpha]_D$ +89 °C (chloroform).

Manzamine C (**443**) [*112693-24-0*], $C_{23}H_{29}N_3$, M_r 547: *mp* 77–82 °C.

15.9. Panuamine and Haliclonadiamine

Papuamine (**444**) and haliclonadiamine (**445**) were isolated from a marine sponge *Haliclona* sp. [424], [425]. The structures were elucidated by spectroscopic studies. The synthesis of (+)-papuamine (**444**) and (−)-haliclonadiamine (**445**) were reported by Bartrett [426] and Heathcock [427]. Papuamine shows antifungal activity, and the alkaloids inhibit the growth of *Candida albicans, Bacillus substilis,* and *Staphylococcus aureus* (1.0–5.0 µg/mL).

Physical Properties

Papuamine (**444**) [*112455-84-2*], $C_{25}H_{40}N_2$, M_r 368: *mp* 167.5–169 °C, $[\alpha]_D$ −150° (methanol).

Haliclonadiamine (**445**) [*117065-24-4*], $C_{25}H_{40}N_2$, M_r 368: oil, $[\alpha]_D$ −18.2° (methanol).

444 Papuamine

445 Haliclonadiamine

Alkoxides → Alcohols, Aliphatic

Alkyd Resins

1. Introduction

Alkyd resins are, literally, polyesters. They are made by condensation polymerization of three types of monomers:

1) Polyols
2) Polybasic acids
3) Fatty acids or triglyceride oils

Because of their distinctive properties, alkyds often are classified separately from other polyesters, as they are in this encyclopedia.

The largest use of alkyds is for surface coatings (paints, enamels, lacquers, and varnishes) in which the resins function as binders, forming a tough, continuous film that adheres to the object coated. Alkyds are the most versatile of coating binders, and they are used extensively in all major categories of coatings: architectural, industrial, and special purpose (see Chap. 6). Despite gradual replacement of alkyds with other types of resins, a substantial fraction of all organic coatings applied worldwide use alkyds as a primary binder or as an additive.

Alkyds are also important ink binders. Other uses include caulks, adhesives, and plasticizers.

Relative to most commercial polymers, alkyd resins often have low glass transition temperatures T_g. Consequently, they are viscous, tacky materials that are difficult to handle. Most often, the handling problems are overcome by dissolving the resins in organic solvents to give solutions that can be poured and pumped.

Because of their low T_g, most alkyds are useful as coating binders only after they are chemically cured to harden the film after the liquid coating has been applied. Curing is accomplished by cross-linking chemical reactions. Cross-linking may result from chemical reaction of the coating film with oxygen in the air or from chemical reaction with a second resin or substance. The second resin, called a cross-linker, is blended with the alkyd at the time of coating manufacture or application. Certain alkyds are added to acrylic and nitrocellulose lacquers, where their role is to plasticize the brittle thermoplastic resins. Alkyds used in this way do not cross-link.

History. Paints containing vegetable oils have been used for at least 600 years. A major goal in the early development of alkyd resins was to combine vegetable oil technology with polyester technology to make improved materials. Probably the first polyester resin was made by BERZELIUS [18] in 1847. It was an intractable product of glycerol and tartaric acid. In 1901 W. SMITH [19] reported a brittle glycerol – phthalic anhydride polymer, and by 1910 workers at General Electric were attempting to develop more tractable materials for electrical end uses. Work was probably hampered by lack of an accepted theory of polymerization, but several patents were obtained.

The General Electric program eventually led to preparation in 1921 of glycerol – phthalic anhydride – fatty acid polymers. By 1926 these polymers were being used commercially as adhesives, and research on their use in coatings was underway [20]. The first account of this work was published in 1929 [21]. A U.S. patent was issued in 1933 [22] but was declared invalid in

10.1002/14356007.a01_409

1935. Technical progress presumably was aided by emergence of polymerization theory in the late 1920s [23], [24].

An important early development was the monoglyceride process for making alkyds directly from vegetable oils, eliminating the expense of preparing and purifying glycerine and fatty acids. In the 1930s, linseed oil was the most common binder for architectural paints, but alkyds were beginning to replace it. Alkyds offered faster drying, less yellowing, and superior protective properties. By 1940 U.S. consumption of alkyds exceeded 4×10^4 t/a.

By the early 1950s, alkyds had become the preeminent binder for coatings. U.S. consumption had reached 2×10^5 t/a and was rising. However, water-based architectural paints were being introduced. These paints generally used polyvinyl or polyacrylic emulsion resins as binders and contained little or no alkyd. During the 1950s, 1960s, and 1970s, water-based paints gradually captured most of the architectural coatings market from alkyd- and oil-based paints. The newer paints were popular because they could be cleaned up with water and were economical to produce because of low petroleum prices. Despite declining use in architectural paints, total use of alkyds continued to increase during most of this period because of rapidly growing use in a huge variety of industrial and special purpose coatings and in inks. Alkyd consumption in the USA reached a plateau at about 3×10^5 t/a in 1960–1980 and then began declining at a rate of about 2 %/a, reaching about 2.3×10^5 t/a in 1996 [25]. Worldwide consumption of alkyds is probably declining at a slower rate and perhaps holding steady.

Alkyd technology is being adapted to meet contemporary needs. Concern about air quality led to development of alkyds for use in high-solids and water-reducible coatings. Rising petrochemical prices have increased interest in all polymers made partly from renewable resources. Besides, alkyds are entrenched in innumerable specialized end uses, so wholesale replacement would be difficult.

Definitions and Classifications. Terminology relating to alkyd resins can be confusing because it has never been uniform and because it has changed considerably over the years. The ASTM defines an alkyd as "a synthetic resin made from polyhydric alcohols and polybasic acids; generally modified with resins, fatty oils, or fatty acids" [26]. The DIN definition is similar [27].

For this article, slightly narrower and more exact definitions have been adopted. They are conveniently represented as follows:

In this article the word "alkyd" is used as both a noun and an adjective. Therefore, "alkyd" and "alkyd resin" are synonymous. This usage is widespread, although some authors feel that only the latter usage is correct.

The scope of this article includes alkyds and modified alkyds. Polyesters are treated under separate keywords (see → Polyester Resins, → Polyesters).

A brief retracing of the history of resin terminology may help clarify some of the terms that may be encountered. "Alkyd" is a respelling of "alcid", a word apparently coined at General Electric for the reaction product of polyfunctional alcohols and organic acids. Therefore, in the 1920s "alkyd" meant what is now meant by "polyester". The resins now called alkyds were called "oil-modified alkyds" during the 1930s. For a time, almost all commercial alkyds contained oil, so the phrase "oil-modified" was redundant and fell out of use. As polyester resins gained popularity in coatings, they began to be called "oil-free alkyds", a term that is now becoming obsolete. In the older literature, the term "glyptal" is found. It is synonymous with "alkyd". It was originally a General Electric trade name.

Today, the term "modified alkyd" usually refers to a resin in which a fourth type of monomer (a modifier) is incorporated in the polymer molecules. This definition is used in this article.

Because alkyds are a large and diverse family of resins, several *subclassifications* are often used. These groupings describe the features that most strongly affect resin properties and end

uses, such as the type and amount of fatty acid and the identity of other components.

Fatty Acid Type. There are two broad groupings:

1) *Drying alkyds* contain enough unsaturated fatty acids to make curing by oxygen possible.
2) *Nondrying alkyds* contain lower levels of unsaturated fatty acids and are not polymerized appreciably with oxygen.

To be more specific, the particular oil used in preparing the resins is often stated.

Fatty Acid Amount. A classification called "oil length" arbitrarily groups alkyds by the amount of oil or fatty acid present. For alkyds made directly from oils, the oil length is given by Equation (1).

$$\text{Oil length} = (\text{mass of oil used to make alkyd resin} \times 100)(\text{mass of reactants-mass of water evolved in process})^{-1} \quad (1)$$

For alkyds made from fatty acids, the formula is amended to correct for the extra mass of water lost (usually about 4 %) during esterification of the fatty acids, i.e., the factor of 100 in Equation (1) is replaced by 104.

Many authors classify alkyds by "oil length", a term apparently derived from terminology in varnish production in which oils were blended with other ingredients such as rosin or phenolic resins. Oil-length classifications are approximate, mainly because the ranges tabulated in Table 1 are standardized in Europe but not, apparently, in the rest of the world. Different authors assign somewhat different dividing points between short and medium, medium and long, etc. Despite being inexact, oil length classifications are used widely. The ranges used in Europe and the USA are listed in Table 1 [28].

Table 1. Percentage of oil in alkyd classes

Oil length	Europe (DIN 55 945)	Common U.S. usage
Short oil alkyds	<40	<45
Medium oil alkyds	40–60	45–55
Long oil alkyds	60–70	55–70
Very long oil alkyds ("alkyd oils")	>70	>70

Other authors, however, give different ranges for the USA; in one case they are the same as STOYE gives for Europe [29]. In view of the ambiguities involved, it is safest to work with the actual oil length numbers, not the verbal ranges.

Other Constituents. When the polyol and polybasic acid are not specified in describing an alkyd, it probably contains glycerol and phthalic anhydride, the most common ingredients. Other ingredients often are mentioned in describing a resin, e.g., "an isophthalic alkyd".

Modified alkyds usually, but not always, are classified according to the generic type of modifer, e.g., "a styrenated alkyd" or "a silicone-modified alkyd".

2. Production

2.1. Raw Materials

Well over one hundred raw materials are used in commercial alkyd manufacture. Each resin contains a minimum of three monomers and often five to seven. Only the most common raw materials are listed here.

Polyols (→ Alcohols, Polyhydric, → Ethylene Glycol, → Glycerol). Alkyds produced by processes that start with triglyceride oils (see Section 2.3) always contain at least some glycerol. Other polyols often are used, leading to alkyds of mixed polyol content.

Processes starting with fatty acids (see Section 2.3) allow the use of any polyol or polyol mixture to achieve the desired spectrum of properties. Glycerol [*56-81-5*] can be used, but less expensive synthetic polyols are a common choice. 1,1,1-Trimethylolpropane [*77-99-6*] is a popular synthetic alternative to glycerol. Pentaerythritol [*115-77-5*], with four hydroxyl groups per molecule, is popular because it builds highly branched polymers and because it is relatively inexpensive. Mixtures of pentaerythritol and ethylene glycol [*107-21-1*] may be used as a low-cost substitute for glycerol.

Polybasic Acids and Their Anhydrides. Phthalic anhydride [*85-44-9*] (→ Phthalic Acid and Derivatives) is used more than any other polybasic acid for reasons of economy and easy processing. Isophthalic acid [*121-91-5*] is often used where superior weatherability and corrosion resistance are required. Cycloaliphatic

diacids, such as 1,4-cyclohexanedicarboxylic acid [*1076-97-7*], are also said to give better weatherability than phthalic acid.Trimellitic anhydride [*552-30-7*] (→ Carboxylic Acids, Aromatic) is used mainly in water-reducible alkyds. Many alkyds contain a small percentage of maleic anhydride [*108-31-6*] (→ Maleic and Fumaric Acids), which is said to reduce resin color and may enhance oxidative cross-linking.

1,2-Polybasic acids are never used as such. Instead, their internal cyclic anhydrides are used. The anhydrides form nominally the same polymer composition as the acids, but they are easier to handle, easier to polymerize, more stable, and less costly. In large-scale operations phthalic anhydride and maleic anhydride are kept hot and are handled in liquid form, an economy not feasible with the high-melting acids.

Triglyceride Oils and Fatty Acids (→ Fats and Fatty Oils, → Fatty Acids, → Drying Oils and Related Products). *Triglycerides* containing unsaturated and mixed fatty acids can remain liquid at temperatures well below 0 °C. For example, linseed oil contains a mixture of C_{18} fatty acids with zero, one, two, and three double bonds per C_{18} chain; it does not freeze at the very cold temperatures to which flax seeds may be exposed. A typical molecule might have the structure:

$$\begin{array}{lll} H_2C-O-\overset{\overset{\displaystyle O}{\|}}{C}(CH_2)_7(CH{=}CHCH_2)_2(CH_2)_3CH_3 & & \text{(linoleic)} \\ \quad | & & \\ HC-O-\overset{\overset{\displaystyle O}{\|}}{C}(CH_2)_7(CH{=}CHCH_2)_3CH_3 & & \text{(linolenic)} \\ \quad | & & \\ H_2C-O-\overset{\overset{\displaystyle O}{\|}}{C}(CH_2)_7CH{=}CH(CH_2)_7CH_3 & & \text{(oleic)} \end{array}$$

The total number of double bonds in a fatty acid, the Wijs iodine number, is measured by titration with iodine [30]. This number, however, correlates poorly with the reactivity of a triglyceride oil toward oxygen, a critical factor for coatings based on drying alkyds. Fatty acid residues containing only one double bond are almost unreactive. Those containing more than one double bond separated by a single methylene group, e.g., –CH=CHCH$_2$CH=CH--, react readily with oxygen and impart drying capablities to the oil or alkyd. Linoleic and linolenic acids have two and three such double bonds, respectively. Conjugated double bonds, e.g., –CH=CHCH=CH--, within the fatty acid are even more reactive.

Nondrying alkyds, for which reactivity with oxygen is unwanted, are made from triglyceride oils that contain a high proportion of saturated fatty acids, such as coconut oil. They can also be made from synthetic fatty acids.

While the fatty acid makeup of each type of oil is somewhat characteristic, the exact composition of the fatty acid mixture may vary widely with soil, climate, strain of plant, extraction process, and other factors. For example, the iodine number of soybean oil may vary from 103 to 151 [30]. Commercial oils are reliably within a much narrower range, for example 128 – 135 for soybean oil [31].

Usually the double bonds of the fatty acids are in the relatively unreactive *cis*, nonconjugated configuration. Certain oils, such as tung, oiticica, and dehydrated castor, contain conjugated and/or *trans* double bonds and are used to make alkyds for fast air-drying and low-bake coatings.

Some of the oils frequently used in alkyds are listed in Table 2 along with their iodine numbers and an indication of the degree of unsaturation of the fatty acids present. The numbers are averages of published data and, of course, are approximate. A wide variety of other oils is used, including tung oil, whale oil, and fish oils from various sources.

The *fatty acids* used in alkyd production are usually made by hydrolyzing (saponifying or "splitting") triglyceride oils to obtain fatty acid mixtures. Linseed oil fatty acid and soybean oil fatty acid [*68308-53-2*] are used widely. The fatty acid composition of the oil is not substantially changed by the hydrolysis process. Some fatty acid producers offer fractionated products that are enriched in particular acids.

An important fatty acid mixture not derived from a seed oil is tall oil fatty acid [*61790-12-3*] (→ Tall Oil). It is a byproduct of kraft pulping. The name derives from the Swedish word for pine. The composition and performance are fairly similar to those of soybean oil fatty acid. The presence of about 10 % of fast-reacting con-

Table 2. Makeup of oils used in alkyds

Oil		Iodine no.	Typical fatty acid composition, % ∗				
			0	1	2	3	4–6
Linseed	[*8001-26-1*]	190	11	18	16	55	–

Soybean	[*8001-22-7*]	132	15	25	52	8	–
Coconut	[*8001-31-8*]	8	91	7	2	–	–

∗ Indicates percentage of fatty acid chains containing zero, one, two, etc., double bonds per fatty acid chain
∗∗ Contains a high proportion of conjugated double bonds

jugated double bonds compensates for its lower iodine number of about 125. Tall oil fatty acid always contains some rosin as an impurity; it is sold in grades specifying the maximum amount of rosin. The 1.5 % and 4 % grades are used widely in alkyds. Tall oil produced in Europe has a somewhat different composition than tall oil produced in North America; resin production formulas developed with one type are likely to fail if the other type is substituted.

Synthetic fatty acids are used in alkyds to a modest extent.

Modifiers (see Chap.4).

Solvents. Immediately after production almost all alkyds are thinned in organic solvent to make them pumpable and pourable. Generally, these solvents are not removed at the time of coating manufacture, and they become part of the coating formula. Medium and long oil types usually are thinned with mineral spirits. Short oil alkyds require more polar solvents, often blends of aromatic hydrocarbon solvents. Alkyds to be used in high-solids coatings are sometimes thinned with ester or ketone solvents, which are efficient viscosity reducers. Water-reducible alkyds are thinned with water-miscible solvents such as 2-butoxyethanol or 1-propoxy-2-propanol.

Many alkyd resin and paint formulas were changed during the 1980s and 1990s to avoid solvents classified in the USA as "hazardous air pollutants" (HAPs). Similar changes were made in other countries.

2.2. Polymerization Theory

When a difunctional acid or anhydride (AA) and a difunctional alcohol (BB) are heated together, a stepwise reaction occurs that builds up linear chain molecules:

Compositions containing short chains (3 to about 20 monomer units per chain) are called "oligomers". Those containing long chains are "polymers". Under ideal conditions polymer chains containing thousands of monomer units can be made. Conditions necessary for formation of very high molecular mass chains include the following:

1) The mixture must be heated long enough to complete the reaction.
2) Equimolar quantities of AA and BB must be present.
3) No alternative reactions may be possible.
4) AA and BB must contain no monofunctional reactive impurities.

The average molecular mass can be deliberately held at lower levels by altering any of the above ideal conditions, for example:

where A represents a monofunctional acid. The actual products of such reactions are mixtures of various chain lengths.

If a trifunctional monomer BBB is added, chain branching occurs:

If substantial amounts of BBB are present, continued polymerization leads to formation of a three-dimensional network, or gel:

One of the goals in alkyd resin synthesis is to prepare structures that are branched but are not quite gelled. A fairly close approach to gelation is needed to form a polymer which readily forms cross-linked networks after application as a coating. However, gelation in the reactor causes a total loss of materials and a difficult clean-up job.

Much research has been directed toward understanding polymerization and developing general principles to help the alkyd formulator achieve the desired degree of polymerization and to optimize properties. Early theories of polymerization were developed by CAROTHERS [23], [29] and by KIENLE et al. [20], [22], [24], [34], [35]. CAROTHERS hypothesized a uniform, stepwise polymerization process. In his model, gelation occurs as the polymer molecular mass approaches infinity. The condition for gelation would be

$$p_g = \frac{2}{F_{av}}$$

where

p_g is the extent of reaction at the gel point and

F_{av} is the average functionality of the monomer mixture.

According to this equation pure difunctional monomers can never gel, but a mixture of glycerol and phthalic anhydride ($F_{av} = 2.5$) would gel at $p_g = 0.8$; that is, it would gel when 80 % of the functional groups have reacted.

In practice gelation usually occurs at lower p_g than predicted by the Carothers theory. To explain this fact FLORY et al. [32], [33] proposed a probabilistic theory: gelation occurs when a relatively small proportion of the monomer molecules first becomes bonded into a three-dimensional network. FLORY's theory is satisfactory for predicting polymerizations of the chemically straightforward monomers used to make polyesters. However, alkyd formulators must deal with monomers that are far from straightforward. Complications include

- Variable starting materials
- Competing side reactions
- Reaction reversibility
- Differential reactivity of the functional groups
- Differential solubility effects
- Nonuniform process conditions

Gradual progress has been made toward a general and reliable theory of alkyd formation by several authors; see, e.g., [6], [38–44]. A completely precise theory is unlikely, mainly because alkyd polymerizations probably are not homogeneous during the late stages of reaction. Most alkyds contain small, soft gel particles as well as soluble material [44], and these gel particles are in some cases essential to the attainment of optimum properties [45], [46]. Despite this difficulty, certain alkyd polymerizations can be accurately modeled with the aid of computers and advanced statistical techniques [47]. Such theoretical methods offer considerable help and insight to the alkyd formulator. They can reduce reliance on empirical trial and error, but they will not completely eliminate it for the foreseeable future.

2.3. Formulation and Process Types; Laboratory Processing

Alkyds are made in batch processes, of which several types have evolved.

Fusion Process Using Fatty Acids. The fusion process starting with fatty acids is the oldest and most straightforward. A representative formulation is given in Table 3 [48].

Table 3. Composition of long oil alkyd

	Equivalents COOH	OH	g	% in alkyd
Soybean fatty acids	1.246	–	349.0	60.0
Pentaerythritol	–	3.545	125.5	21.5
Phthalic anhydride	2.000	–	148.0	25.4
Totals	3.246	3.545	622.5	106.9
H_2O			−40.4	−6.9
Theoretical yield of resin			582.1	100.0

Like nearly all alkyd formulations, it contains an excess of hydroxyl groups, 9.2 % in this case. This excess is essential to assure that the rate of viscosity increase will be controllable as the polymerization process approaches completion. To visualize the consequences of not using an excess of OH groups, suppose that exactly 3.246 equivalents of pentaerythritol have been used. The F_{av} would have been 2.07, and CAROTHERS' theory predicts an exponential increase in viscosity as the reaction approaches completion, ending in gelation at $p_g = 0.96$. As FLORY's theory and practical experience demonstrate, gelation would actually occur at lower p_g. Therefore in the late stages of reaction, viscosity would be increasing rapidly and exponentially. However, the 9.2 % excess of OH groups assures that the number average chain length will remain modest even when nearly all of the carboxyl groups have reacted, limiting viscosity at the desired level. Chain lengths of individual molecules in the resin will vary from the oligomer to the high-polymer range.

Viscosity could be controlled by using an excess of acid, but inferior coatings would result because of moisture sensitivity imparted by the unconverted COOH groups in the film. Unconverted OH groups impart less moisture sensitivity, and they play a useful role in certain cross-linking reactions (see Chap. 3).

To prepare the above resin on a *laboratory scale* the ingredients are placed in a round-bottom reaction flask, heated at about 240 °C, and stirred mechanically. Inert gas (N_2 or CO_2) is passed through the reaction mass to facilitate water removal; the water is condensed and measured to estimate the extent of reaction. As the reaction approaches completion (5 – 10 h), samples are removed and the acid value and/or viscosity are measured. When the desired degree of reaction has been reached, the reaction mass is cooled slightly and is diluted with about an equal volume of mineral spirits.

Fusion Process Using Triglyceride Oils. The fusion process starting from triglyceride oils is often called the *alcoholysis* or the *monoglyceride process*. It is popular because the oil provides an economical source of all of the fatty acid and part of the polyol. It is a two-stage, batch process:

The first, or alcoholysis, stage is an ester interchange reaction. Equilibrium is reached within an hour or two at sufficiently elevated temperature when the reaction is catalyzed by litharge (PbO) or by certain Li or Ca salts. Although the product is called a monoglyceride, it is actually a mixture of isomers of mono-, di-, and triglycerides and of glycerol. Polyols other than glycerol often are used and yield even more complex mixtures. In the second stage polybasic acids or anhydrides are polymerized with the monoglyceride mixture to form the resin. Other ingredients often are added during the second stage.

Procedures and equipment for laboratory preparation are generally similar to those used for the fatty acid process.

Both fusion processes suffer from several practical difficulties. To assure reasonable process rates the water of reaction must be removed by "sparging" the reaction mass with a stream

of inert gas. Without sparging, process rates are slow because the esterification reaction is highly reversible. With sparging, however, the gas stream sweeps vapors of phthalic anhydride and polyol out of the reaction mass. These materials may be lost altogether or they may condense in the upper parts of the apparatus from which they may fall back into the reactor, causing dark or nonuniform product.

Solvent Processes. To overcome these problems solvent processes are used widely, both with fatty acid and triglyceride starting materials. In these processes a few percent of unreactive, water-immiscible solvent is added to the formulation. Commercial xylene, also called xylol (mixed dimethylbenzenes and ethylbenzene, *bp* 138 – 140 °C), is used commonly. Typically a stirred alkyd polymerization mass containing 4 % xylene will boil vigorously at about 250 °C. The xylene vapors form an azeotrope with water and carry it out of the reactor. Usually the vapor stream is passed through a "partial condenser" operated at about 100 °C; this allows water vapor to escape, but it condenses most of the xylene and almost all of the monomers and returns them to the reactor. Whether or not a partial condenser is used, the vapors are condensed. Water and xylene separate into two layers, and the xylene is returned to the reactor.

Laboratory equipment for solvent processing has been described in detail [49]. Losses of xylene and of monomers can be minimized with proper operation, and uniform products can be produced.

2.4. Manufacture

A variety of equipment for alkyd production has been described [5], [8], [50]. Equipment for *solvent processing* will be described here because the trend is in that direction. However, fusion processes, which require simpler equipment, often produce satisfactory products. The fusion process is preferable for isophthalic alkyds.

Figure 1 shows a versatile configuration designed for the solvent process. The reactor typically would be constructed of no. 316 stainless steel. Capacity of commercial-scale reactors ranges from 2 to 35 m^3. A turbine agitator driven by a powerful electric motor is necessary. Heating and cooling generally are accomplished by a heat-transfer fluid flowing either through a jacket around the reactor (as shown in Figure 1) or through coils within the reactor. High-pressure steam and gas-flame heating have been used but are less satisfactory and more hazardous.

Whereas the reactor and overhead shown in Figure 1 are the heart of an alkyd plant, other equipment is needed for efficient, large-scale production. Such equipment includes the following:

1) Raw material storage and metering equipment (phthalic anhydride often handled in hot, molten form)
2) A manhole in the reactor top for adding solids and to provide access for cleaning
3) A heater for heat-transfer fluid
4) A thin tank about 2.5 times as large as the reactor, equipped with a condenser and agitator
5) Product storage tanks and drumming equipment
6) Environmental control equipment, including incinerators for gaseous and liquid waste
7) Filters
8) Safety and fire protection equipment, including rupture disks, blowout vents, and sprinklers

Automated alkyd reactors have been installed in Europe, North America, and Asia [51]. Improved safety, quality, and productivity are claimed. However, several factors have discouraged retrofitting of reactors to automate them. Although the necessary microprocessors are relatively inexpensive, automation requires costly feedback systems and servomotor driven valves. Detailed process studies are necessary to program the microprocessor to deal with all contingencies.

3. Film Formation by Coatings Based on Alkyd Resins

There are two mechanisms by which a liquid coating can be transformed into a tough, protective film after it has been applied:

1) Lacquer drying by simple solvent evaporation

Figure 1. Alkyd solvent-processing equipment with partial condenser (adapted from [30])

2) Chemical cross-linking by reaction of the polymeric binders to form a cross-linked polymer network

Coatings based on alkyd resins often depend on both mechanisms to some degree. Chemical cross-linking plays a vital role in converting a soft, tacky alkyd into a hard, tough film.

Drying Alkyds. The majority of alkyd coatings are designed for film formation at ambient or slightly elevated temperatures. The chemical mechanism of curing involves autoxidation of the unsaturated fatty acid residues in the resin. This chemically complex process has been studied extensively [52–58], but it is not yet completely understood. Most of the studies have involved model compounds such as monoesters of

fatty acids rather than the more complex alkyd resins.

Autoxidation of alkyds is a chain reaction that proceeds by a free-radical mechanism. A key step is the formation of a hydroperoxide on an allylic methylene group:

The hydroperoxide is capable of several further reactions, some of which lead to formation of stable, covalent bonds with sites on other resin molecules. This bonding builds up a three-dimensional polymeric network, and a tough film is formed.

Small amounts of catalysts (driers) that promote autoxidation and cross-linking are added to drying-type alkyd coatings. Driers are generally mixtures of oil-soluble salts of Co, Mn, Zr, Ca or other metals [59]: soluble Pb salts are also effective but have been banned in many countries.

Fatty acid chains containing only one double bond are autoxidized slowly. Those containing allylic methylene groups activated by two double bonds react over 100 times faster. Reaction sequences probably involve rearrangement and isomerization of the double bonds, for example:

Studies on model compound [56–58] confirm the mechanism shown above for the early stages of cross-linking, but reveal that subsequent film-forming reactions are extremely complex and beyond the scope of this article.

Useful drying rates are achieved only if appreciable concentrations of polyunsaturated fatty acid residues are present. Soybean, safflower, sunflower, and tall oil alkyds are about the least unsaturated that dry well. These oils have high linoleic acid (two double bonds) content but relatively low levels of fatty acids with three or more double bonds. They are preferred for decorative coatings where resistance to yellowing is desired and moderate cross-linking is adequate.

Higher levels of cross-linking and therefore better protective properties are achieved by use of fatty acids or oils with substantial contents of triply unsaturated fatty acid residues (linseed or tung) or of those containing multiple unsaturated fatty acid residues (fish oils). Blends of fatty acids or oils are used to reduce cost and sometimes to minimize premature cross-linking during alkyd manufacture.

Drying rate is often an important consideration. Oils containing two conjugated double bonds dry faster than those containing similar levels of nonconjugated double bonds. Thus, chemically modified oils and fatty acids with two conjugated double bonds (dehydrated castor oil and conjugated tall oil fatty acids) find considerable use. Fastest of all are oils that contain fatty acids with three conjugated double bonds, such as tung oil.

Rates of autoxidation are useful above about 0 °C and sharply increase with increasing temperature. A significant advantage of drying oil alkyd-based paints over latices is that they can form satisfactory films when applied at 0 °C or even a bit below.

Drawbacks of all alkyd paints paints include a tendency of the films to turn yellow and become brittle with age. Their low permeability to water can also lead to blistering when painted on wood. Use of high-linoleic, low-linolenic oils such as safflower and sunflower can minimize these problems, but can not eliminate them. Short oil alkyds are used in applications where rapid partial drying is needed. Although they have less cross-linking capability than longer oil types, they quickly develop some degree of hardness by lacquer drying as the solvent evaporates. Quick drying is desirable in many manufacturing situations, as it permits gentle handling within 15 – 30 min after coating. Film properties improve for several days or weeks as the slower cross-linking process occurs.

Nondrying Alkyds. Alkyds are used extensively in industrial coatings that are designed to be cured at elevated temperatures (baking or stoving enamels). Such enamels are usually blends of alkyds with aminoplasts, e.g., alkylated melamine – formaldehyde or urea – formaldehyde resins. Cross-linking occurs by

acid-catalyzed condensation of the OH groups of the alkyd with the aminoplast:

Other chemical cross-linkers can be blended with alkyds. For example, alkyd – polyisocyanate blends are used as binders for two-package, ambient temperature curing polyurethane coatings.

Alkyds for baking enamels do not need to be autoxidizable and often are made from oils containing only saturated fatty acids, coconut, for example. Soybean and tall oil alkyds often are used in alkyd – amino enamels; such enamels cure by a mixture of condensation and autoxidative cross-linking.

Polyvalent metal alkoxides, such as $Al(OC_4H_9)_3$, can serve as trifunctional cross-linkers. They react with hydroxyl groups on the alkyd resin to form $Al(O–alkyd)_3$ structures within the film. This expedient can enhance hardness and through-cure of the paints.

Nondrying alkyds are used as plasticizers in lacquers. Their role is to soften high molecular mass thermoplastic resins that otherwise would be too hard and brittle for coatings use. Examples are nitrocellulose – alkyd blends for furniture finishes and acrylic – alkyd blends for automotive refinish lacquers. Note that in Europe the term "lacquers" is frequently applied to all types of organic coatings, while in North America the term tends to be limited to coatings made from thermoplastic, non-cross-linking binders.

4. Modified Alkyds

Roughly one-fourth of commercial alkyd usage is of modified alkyds, resins in which modifiers are at least partly interpolymerized with the usual alkyd monomers. The more important types are described in this section.

Chain-stopped alkyds contain aromatic monobasic acids (see Section 2.2), such as benzoic acid [*65-85-0*] or 4-(1,1-dimethylethyl)benzoic acid (*p-tert*-butylbenzoic acid) [*98-73-7*]. These modifiers improve lacquer-dry characteristics and harden films. However, because they do not participate in covalent cross-linking, the films tend toward brittleness.

Inclusion of monobasic acids during polymerization reduces F_{av}; to compensate, highly functional polyols such as pentaerythritol are used. Because pentaerythritol and benzoic acid are relatively inexpensive, low-cost resins with reasonably good properties are attainable. Uses are diverse, a major one being traffic-control striping. Chain-stopped alkyds are useful in high-solids coatings (see Chapter 5).

For premium-quality chain-stopped resins, 4-*tert*-butylbenzoic acid affords an excellent combination of fast dry and film plasticity. However, use of this modifier is limited by concerns about its potential for long-term health effects.

Styrenated alkyds are made in a two-stage process [54], [60]. First a drying oil alkyd is produced using a formulation designed to limit molecular mass. The resin is then thinned, usually with xylene, and styrene [*100-42-5*] is added to the solution. Addition of a free-radical initiator starts the second stage of the process, the addition polymerization of the styrene. This step is effected at higher temperature (about 140 °C) than most addition polymerizations, conditions that favor grafting of polystyrene segments onto the alkyd. The product is a mixture of graft copolymer, ungrafted alkyd, and homopolystyrene [61]. Apparently sufficient grafting occurs to "compatibilize" the mixture.

Styrene content ranges up to 60 %. The homopolystyrene ($T_g \approx 100$ °C) segments impart hardness, chemical resistance, and very fast lacquer dry characteristics. However, high levels of styrene reduce weatherability and toughness.

Acrylated alkyds are made by a similar process using acrylic or methacrylic monomers in place of styrene [62]. These monomers are more costly than styrene, but their presence improves resistance to sunlight. For example, an alkyd modified with methyl methacrylate [*80-62-6*] (homopolymer $T_g \approx 105$ °C) would be simi-

lar in most properties to a styrenated alkyd but would be more weatherable. Alkyds modified with lower T_g acrylic or methacrylic monomers can be made readily. They are less important because they offer few advantages over unmodified alkyds.

Other olefinic monomers, such as acrylonitrile [*107-13-1*], α-methylstyrene [*98-83-9*], and mixed 3- and 4-vinyltoluene (VT), are used commercially to modify alkyds. The latter mixture affords the commercially important "VT alkyds", which lacquer dry nearly as fast as styrenated alkyds but have better film properties. Uses include fast-dry industrial enamels and aerosol paints.

Silicone alkyds are prepared by interpolymerizing hydroxyfunctional organosilicone oligomers with alkyd resins [63]. Methyl/phenyl-substituted silicones are used. The proportion of silicone ranges from 15 to 55 %. These premium quality resins have superior resistance to heat and weather. Drying oil silicone alkyds are used in heat-resistant coatings such as stove enamels and in exterior applications in which prolonged retention of properties and appearance saves substantial cost by reducing the frequency of repainting, e.g., petroleum storage tanks. Blends of nondrying silicone alkyds with melamine resins have been used in coil-applied coatings for exterior siding.

Thixotropic alkyds are modified at high temperatures with an oil-miscible polyamide resin, for example, a polymer [*51178-84-8*] of octadecadienoic acid dimer [*6144-28-1*] and 1,2-diaminoethane [*107-15-3*]. Proportions and reaction conditions must be carefully controlled [64]. Paints containing these resins are viscous, but their viscosity drops under mechanical shear and then recovers when the shear is removed. It is unclear from published information whether their behavior is simple shear thinning (near instantaneous recovery when shear is removed) or genuine thixotropy (time-delayed recovery). Regardless of methanism, the paints resist running and sagging when brushed or sprayed in thick coats. Applications include bridge and marine paints.

Uralkyds are usually air-drying compositions in which part of the polybasic acid is replaced by a polyfunctional isocyanate, most commonly toluene diisocyanate [*26471-62-5*] (→ Isocyanates, Organic) to form a polyester – polyurethane interpolymer. The resins are usually made in a two-stage process, the reactive toluene diisocyanate being added in the second stage at relatively low temperature.

An excess of OH groups is used so that all of the isocyanate reacts to form urethane linkages. Cross-linking is accomplished by the usual autoxidative mechanism. Presence of the urethane linkages imparts outstanding toughness, water resistance, and abrasion resistance; thus, urethane alkyds are used in premium-quality varnishes, for example, for gymnasium floors. A drawback is that resins containing toluene diisocyanate are brownish and yield yellowish varnishes that darken with age. This problem can be almost eliminated by use of the more costly aliphatic polyisocyanates in place of toluene diisocyanate.

A second class of uralkyds is prepared with a deficiency of OH groups so that unconverted isocyanate groups are present in the resin. After application these resins cross-link by reaction of atmospheric moisture with the isocyanate groups. They form exceptionally tough films. However, the coatings are difficult to apply and may cause skin irritation.
